Legionnaires' Disease, Pontiac Fever, and Related Illnesses

Paul H. Edelstein

Legionnaires' disease (LD) is an acute pneumonic illness caused by gram-negative bacilli of the genus *Legionella*. Pontiac fever is a febrile, nonpneumonic, systemic illness closely associated with, if not caused by, *Legionella* spp. infection.

HISTORY

LD first was recognized as a distinct clinical entity when it caused an epidemic of pneumonia at an American Legion convention in Philadelphia in 1976 where 221 people were affected and 34 died.⁸³ Investigators were unable to determine the exact cause of the outbreak immediately, and this mystery provoked considerable fear and widespread speculation about the cause. Approximately 6 months later, two investigators at the Centers for Disease Control and Prevention (CDC), Joseph McDade and Charles Shepard, announced that they had discovered the etiologic agent, a fastidious gram-negative bacillus.¹⁴¹ Researchers determined subsequently that both the organism and the disease had been studied previously as long ago as the 1940s, but had been forgotten.^{47,65,191} Because of the historical association with the American Legion convention, this disease now is called LD, and the etiologic agents belong to the family Legionellaceae.

ETIOLOGIC AGENT

Legionella is the only genus in the family Legionellaceae. Sixty different species of *Legionella* are now recognized (Table 137.1). The closest pathogenic relative of the Legionellaceae is *Coxiella burnetii*, the agent of Q fever. *Legionella pneumophila* was responsible for the 1976 Philadelphia epidemic and causes most cases of LD.^{47,52,65,122,130,191} *L. pneumophila* serogroup 1 is estimated to cause 70% to 90% of all cases of LD in previously healthy people.^{54,137} *Legionella* spp. other than *L. pneumophila*, and serogroups other than *L. pneumophila* serogroup 1, cause 25% to 40% of nosocomial outbreaks of LD; of these, *L. pneumophila* serogroups 4 and 6, *Legionella micdadei*, and *Legionella dumoffii* are the most common.^{104,211} *L. pneumophila* and *Legionella longbeachae* are the only two *Legionella* spp. that normally infect nonimmunocompromised patients.

The Legionellaceae are obligately aerobic, mesophilic, motile, L-cysteine auxotrophic gram-negative bacilli with variable oxidase and

catalase reactions.⁶⁴ Genomes of multiple *Legionella* spp. strains have been sequenced, revealing that these bacteria harbor certain eukaryotic-like genes, several secretion systems, remarkable plasticity, and the presence of mobile elements.^{27,91,132} Approximately 10% of the approximately 3.5-Mb genome is devoted to strain-specific genes.^{25,38,41}

Antigenic relationships among different *Legionella* spp. and among serotypes of the same species are complex.¹⁹¹ The serologic typing scheme is based on surface antigens (O antigens), which primarily are lipopolysaccharides. These surface antigens are shared by different species and, in rare cases, by other gram-negative bacilli, such as *Pseudomonas* spp. Identifying an unknown strain by use of serologic methods alone may lead to incorrect identification. Cross-reactions also may be observed in testing for human antibodies to *Legionella* spp. Patients with infections caused by some *Pseudomonas* spp. strains, *Campylobacter jejuni*, and other gram-negative bacilli may develop antibodies to *Legionella* spp.⁶¹

Identification of *Legionella* spp. other than *L. pneumophila* often requires the capabilities of a research, or national reference, laboratory that performs molecular-based identification. However, isolation and presumptive identification of *L. pneumophila* should be within the capabilities of most clinical laboratories.⁶⁴

Legionella bacteria are ubiquitous in the aqueous environment and can be found, often in high concentrations, in lake water, ponds, bathing water, hot water tanks, hot water plumbing, and air conditioning cooling towers.¹⁹¹ Optimal growth temperature ranges from 28° to 40°C (82°–104°F). The natural hosts and reservoirs of environmental *Legionella* bacteria are freshwater amoebae, such as *Acanthamoeba* and *Hartmannella*.⁷⁸ Factors that promote the environmental growth of *Legionella* include the presence of other microorganisms, the use of plumbing materials that promote bacterial growth, stagnation, and warm temperatures.¹⁹¹ In the home, older municipal water distribution systems, the use of electric rather than gas water heaters, and the use of well water all appear to promote the presence of *Legionella* in water.^{78,185} In the particular case of *L. longbeachae*, amoeba-laden potting soil exposed to warm temperatures allows multiplication of the bacterium to high concentrations.²⁰⁶ Most newly discovered *Legionella* spp. have been environmental isolates not associated with clinical illness.⁷⁸

Many bacterial virulence factors have been described, the most important of which is the Dot/Icm complex. This complex comprises 26 genes that form a type IV secretion system that is required for *L.*

*Isolated from humans but unlikely to have caused disease.

pneumophila growth within macrophages. *L. pneumophila* is not killed actively by macrophages. The Dot/Icm complex allows the bacterium to evade normal phagolysosomal trafficking and bacterial destruction by injecting effectors into the host macrophage within minutes of the time of initial bacterial-macrophage contact. More than 300 injected effectors of *L. pneumophila* have been described, but only a few have been fully characterized functionally.^{81,109,156} Other *Legionella* spp. have different predicted effectors, with at least 5800 different predicted effectors, and only seven predicted effectors shared among 38 different species.²⁷ The end result is that the normal host processes are hijacked into providing an intracellular compartment for the bacterium that associates with endoplasmic reticulum.^{43,150,175} Other bacterial virulence factors include a variety of enzymes, iron binding proteins, miscellaneous proteins enhancing intracellular growth, and survival or invasion.⁴³ An important virulence factor for *L. pneumophila* serogroup 1 is a lipopolysaccharide 8-O-acetylase of unknown pathogenic mechanism of action; bacterial strains with this acetylase constitute the majority of *L. pneumophila* clinical isolates yet are uncommon in the environment.³⁷

Availability of intracellular iron appears to play a key role in the growth of intracellular *L. pneumophila*. Interferon- γ , the production of which is increased during *L. pneumophila* infection of macrophages, downregulates the number of iron-binding receptors on macrophages, which has the effect of decreasing the availability of intracellular iron and hence limiting intracellular growth of the bacterium.²⁹

L. pneumophila is serum resistant.¹⁹¹ High-titer antibody promotes phagocytosis but may not enhance killing. Macrophage activation factors possibly are more important than is antibody in promoting phagocytosis and bacterial killing.¹⁰⁷

EPIDEMIOLOGY

Incidence and Frequency

National passive LD surveillance has been initiated through the CDC by using serologic, culture, and mainly urine antigen testing. Cases reported to the CDC from 2000 through 2009 included a total of 22,418 cases, of which there were 204 (1%) pediatric cases, with 39% of those in children less than age 10 years.³⁹ In an earlier CDC report spanning 1990 to 2005, 375 pediatric cases were reported, comprising 1.7% of the total number of reported cases. The most pediatric cases, 44.3%, were in the 15- to 19-year age group, followed by those younger than 1 year of age, at 18.1%.¹⁵⁵ In 2015, the CDC reported 5315 cases of LD, a number reflecting an approximate doubling of reported cases from the prior decade.

Pediatric LD rarely appears to be the cause of pneumonia in otherwise healthy children.* Fewer than 20 well-documented cases of LD have been reported in otherwise normally healthy children older than a month, and fewer than 100 culture-confirmed cases have been reported in immunosuppressed children.[†]

A CDC study on the epidemiology of LD in children from 1984 through 2004 found that 66 of 6575 cases (1%) of LD reported during the period occurred in children younger than 19 years of age. The median age was 11 years; 72% reported a health care exposure, 30% had at least one risk factor for the infection, 26% of cases were associated with an outbreak, and 22% died.³ The very low frequency of LD in US children has also been observed in children with pneumonia in China, Kenya, Gabon, and Germany.^{23,40,124,205}

A retrospective serosurvey of 500 patients with pneumonia, 83% of whom did not need hospitalization, found that only five of the 132 patients younger than 15 years of age had significant antibody titers against *L. pneumophila*, and none developed seroconversion.⁸² The estimated incidence of LD in the overall population was approximately 12 per 100,000 per year. Several prospective serologic studies of children with pneumonia found that LD constitutes approximately 1% of the diagnosed causes of pneumonia.^{45,159,173} This rate is approximately the same as the 0.5% to 4% frequency found in the adult population.^{47,137,191} LD is not a major cause of pneumonia in either children or adults.

*References 6, 13, 21, 33, 34, 45, 51, 85, 105, 108, 126, 144, 165, 181, 190.

†References 1, 9, 21, 22, 32–34, 45, 48, 69, 76, 93, 94, 112, 119, 121, 123, 128, 129, 154, 163, 169, 182, 194, 198, 207.

The frequency of LD in immunosuppressed children is unknown, although it is clear that immunosuppressed children can be at high risk for this disease. LD has been reported in children with acute leukemia or chronic granulomatous disease, after bone marrow or solid organ transplantation, or after treatment with corticosteroids for other reasons.⁵ Nosocomial or community-acquired LD has been reported in several “immunologically normal” infants, who may have had some degree of immunocompromise that predisposed them to this disease.^{46,77,85,105,106,115,126,154,169}

Neonates appear to be at increased risk for acquiring nosocomial, water birthing–related, and community-acquired LD.^{84,94,129,146,167,179,189,196,204,209} *Legionella*-contaminated nursery and home humidifiers have been implicated as environmental sources in both nosocomial and sporadic LD cases in neonates and infants.^{21,209} Neonatal LD acquired from formula made with tap water has also been reported.²⁰⁴ As much as possible, neonates should be protected from environmental sources of *Legionella* that can be inhaled or aspirated.

More than 100 cases of Pontiac fever in children have been reported in outbreaks of this disease.^{26,90,110,113,133} The risk for acquiring Pontiac fever was found to be greater for younger people in one outbreak,¹¹⁰ which was just the opposite finding of another outbreak investigation.¹¹³ The true frequency of Pontiac fever in children is difficult to know because the diagnosis is impossible to make with certainty in the sporadic form. One hotel hot tub–related outbreak of both LD and Pontiac fever in families and attendees of a youth athletic event found that the median ages of patients with LD and Pontiac fever were 6.5 and 15 years, respectively.²⁶

Several serosurveys found asymptomatic elevations of *L. pneumophila* antibody in widely varying frequency. In one study, about one-half of 52 children studied developed an increase in antibody titer unrelated to acute illness over a period of several years.⁶ Another study found that 15% of 126 children sampled had antibody titers to *L. pneumophila* of 256 or higher, a finding that was not significantly different from titers seen in an adult control population.¹⁴⁹ The striking finding was that the antibody titers rose with age, doubling each year until age 3 years, when the values plateaued; this finding held even when patients with pneumonia were excluded. The significance of these elevated antibody titers in children without documented pneumonia is unclear, and it can be interpreted as cross-reactions to other colonizing or infecting bacteria, asymptomatic infection, or atypical disease.

Several investigators have examined the question whether atypical disease caused by *Legionella* occurs in children using poorly specific serologic tests. Italian physicians found that two children with acute, reversible cerebellar ataxia developed significant antibody titer changes to *L. pneumophila*.¹⁵⁸ Another Italian study found two children with pericarditis who had significant antibody changes.¹⁸³ None of 140 British infants with sudden death had measurable antibodies to *L. pneumophila*, despite suggestions that they could be linked.²⁰² Three studies have shown that children with cystic fibrosis have higher antibody levels to *Legionella* than do normal children, although these data are suspect because of known cross-reactions between *Legionella* and *Pseudomonas aeruginosa*.^{44,67,116} Thus despite several epidemiologic surveys, the prevalence of atypical *Legionella* infections in children is unclear.

In adults LD incidence figures vary widely, most likely related to the insensitivity of passive reporting systems and the vigor of diagnostic testing. The highest reported incidence rates, between 187 and 375 LD cases per million population per year, were reported from a 2008 prospective study of community-acquired pneumonia in Germany, where special efforts were made to capture all cases and to use sensitive diagnostic tests.¹⁹⁹ A significantly lower incidence has been reported in France (20 cases/million per year), where surveillance is passive but disease reporting is mandatory.³¹ The reported rate in the United States, 17 cases per million per year, is lower, most likely because of a reliance on passive surveillance and limited diagnostic testing for the disease.³⁹ Estimates based on serologic surveys range from 20 to 200 cases per million population per year.^{47,171,191} A prospective study in Ohio found that the incidence of LD requiring hospitalization was approximately 60 per million per year, in what is thought to be a geographic region with

an above-average frequency of the disease.¹³⁸ Estimates of the proportion of adult pneumonias caused by LD range from 1% to 25%, with a reasonable mean of 3%.¹³⁷ Mild or atypical *Legionella* infection certainly occurs in adults, although the exact incidence is unknown. On the basis of serosurveys, asymptomatic infection may occur in adults. Neither oropharyngeal colonization nor a carrier state has been documented.²⁴

Although LD is often thought of as an epidemic disease, it is actually more common as a sporadic disease. One European study showed that sporadic cases represented approximately 92% of all 5960 reported LD cases from 2007 through 2008, similar to the findings in the United States.^{39,114}

Risk factors for acquisition of LD can be divided into two main categories: those that increase exposure to contaminated water and those that suppress pulmonary defense mechanisms.^{47,191} Included in the former category are occupational or residential exposure to warm or stagnant water, traveling and residence in hotels, and stays in hospitals with contaminated water distribution systems; a risk factor for residential acquisition of disease is the use of well water.¹⁸⁵ Weather may be a risk factor in some regions, with increased humidity or rain implicated in a few studies.⁸⁰ Included in risk factors that suppress pulmonary defense mechanisms are surgical procedures requiring general anesthesia, administration of glucocorticosteroids, cigarette smoking, chronic lung disease, and diseases or therapies that compromise the innate or cellular immune systems. Use of biologic response modifiers, especially tumor necrosis factor antagonists, is a significant risk factor for LD.^{135,195} Alemtuzumab treatment is also a likely significant risk factor for LD. Male patients are more than twice as likely as female patients to develop the disease, perhaps as a result of the greater male prevalence of cigarette smoking and chronic lung disease. Middle-aged and older people also are at significantly higher risk than are younger people, as exemplified by data from the United States for 2000 to 2009; the incidence rates (per million/year) were 0.2, 0.3, 1.3, 3.6, 8.1, 14.4, and 26.6 for people younger than 9, 10 to 19, 20 to 29, 30 to 39, 40 to 49, 50 to 59, and older than 80 years of age, respectively.³⁹ Other than exposure to aerosols of contaminated water, no particular predisposing factors for the development of Pontiac fever have been identified. LD is not contagious, and transmission from patients to staff or other patients has never been documented.

Disease Outbreaks

Multiple epidemics of LD and Pontiac fever have been recognized.^{22,47,90,191} In the case of LD, most outbreaks have occurred in residents, employees, or visitors to large buildings; or in urban settings with exposure to aerosolized water from fountains and cooling towers. Hotels, hospitals, museums, factories, retail stores, office buildings, and housing complexes have all been implicated in LD epidemics. Nosocomial LD has been reported in hospitals throughout the world. Disease reservoirs and disseminators have been potable water distribution systems, air conditioning cooling towers, hot tub spas, decorative fountains, industrial water systems, and others.^{47,191} Outbreaks have been ended by disinfection of water and cooling tower systems through hyperchlorination or pasteurization.^{47,191} In some of these outbreaks, disease occurred for many years until effective disinfection procedures were used. Attack rates in LD epidemics consistently have been less than 5% overall. Incubation periods ranging from 2 to 19 days have been observed, with median incubation periods of 4 to 6 days and average ranges from 2 to 10 days.

Pontiac fever outbreaks generally have been associated with exposure to an aerosol of warm water contaminated with *Legionella*.^{89,118,191} Examples include whirlpool baths, an engine assembly plant using contaminated water to cool machine lathes, and a health department building in which condensate in the air conditioning system was contaminated. The attack rates in Pontiac fever outbreaks have been high, in the range of 95% to 100%. The incubation period is short, from 12 to 36 hours.⁸⁹

PATHOLOGY, PATHOGENESIS, AND IMMUNITY

Very good, but indirect, epidemiologic and pathologic evidence suggests that LD infection results from inhalation of an aerosol.^{47,191} The bacterial form that causes infection is unknown, with possibilities including a

⁵References 48, 69, 99, 112, 119, 121, 127, 163, 164, 176, 178, 186, 192.

sporelike form, intra-amebal bacteria, bacteria enmeshed in biofilm, and bacteria released from biofilm.^{78,87,125} Some patients have acquired LD after aspiration of *Legionella*-contaminated tap water, rather than by aerosol inhalation.^{19,111,136,197}

In guinea pigs infected by the aerosol route, multiplication of *L. pneumophila* begins within 16 hours.⁴⁹ Bacterial multiplication occurs within the alveolar macrophage, although growth in respiratory epithelial cells may also occur. Cell culture studies show that multiplication occurs only in cells and not in the extracellular tissue culture medium.¹⁰⁷ This intracellular location of bacteria protects them from serum factors such as antibody and complement, as well as from the effects of those antimicrobial agents that are not concentrated in cells. Killing of *L. pneumophila* within macrophages in cell culture is limited by failure of phagolysosomal acidification and fusion.¹⁰⁷

L. pneumophila avoids macrophage killing by injecting phagosomal maturation-altering compounds into its host cell within minutes of initial contact by using the Dot/Icm type IV secretion system.¹⁰⁹ An additional mechanism involves shedding of bacterial flagellin into the host cytosol, which acts through the innate immune system to alter macrophage killing of the bacteria.¹⁷² In the late phases of bacterial multiplication in macrophages, the bacteria change phenotype to enable infection of the next susceptible macrophage, thereby becoming highly motile, quite small, and more resistant to antimicrobial agents.^{10,145} The *L. pneumophila*-containing vacuole becomes huge, occupying almost the entire volume of the macrophage, over a period of a few days. The bacteria escape from the presumably nutrient-depleted macrophage by inducing cellular apoptosis and can then infect available uninfected macrophages.² Innate macrophage resistance to bacterial infection may be mediated by Toll-like receptors, in particular TLR-2 and TLR-5, and perhaps TLR-4.^{100–102} Acquired macrophage resistance to infection derives from activation by interferon- γ and the resultant downregulation of available iron stores.²⁸ Tumor necrosis factor- α plays a very important role in host defense to infection.¹⁴²

Polymorphonuclear leukocytes neither ingest nor kill the organism effectively in vitro, although animal studies suggest that they may form the bulwark of initial host defenses.⁴⁹ Clinical evidence suggests that leukopenic hosts without concomitant macrophage dysfunction are not high-risk candidates for LD, although they may be at higher risk than is the normal population.^{35,65}

Lung histopathologic findings in LD show intense intra-alveolar inflammation.¹⁹¹ Airways larger than the terminal bronchioles are not affected. The interstitial spaces generally are uninvolved, although necrosis of alveoli may bridge the interstitial spaces. The alveoli contain a variable mixture of polymorphonuclear leukocytes, alveolar macrophages, and necrotic debris. Hemorrhage is observed, as are microabscesses. Later, fibrin formation and a histiocytic predominance occur.

Gross lung changes evolve in the classic pattern of lobar pneumonia, with first red and then gray hepatization.¹⁹¹ Lymph nodes are involved occasionally. The lung segments involved may be subpleural, a finding that sometimes suggests septic or bland infarction to the clinician. The pleural space is involved variably and seemingly is more prone to infection in immunosuppressed patients. One of the most striking pulmonary findings is the usual absence of significant intrabronchial exudate. This absence of intrabronchial exudate and the lack of bronchial inflammation may mislead clinicians to exclude bacterial pneumonia.

Despite frequent signs and symptoms of extrapulmonary disease in patients with LD, no specific extrapulmonary pathologic findings have been identified.¹⁹¹ In fatal cases, organisms often can be recovered or detected in the liver or spleen. Occasionally, patients have nonbacterial endocardial vegetations. Some patients have hilar and paratracheal adenitis. Patients may have metastatic foci with abscesses in almost any location, including the myocardium, pericardium, peritoneum, brain, kidney, bowel wall, perirectal region, prosthetic and native heart valves, muscle and skin, and hemodialysis shunts (Box 137.1).^{65,161,191} Bacteremia is rarely detected, although molecular studies and clinical findings suggest that it is common.^{65,151,191} Elaboration of toxins by *Legionella* has been postulated to account for some aspects of the systemic disease, but supporting evidence is not convincing.¹⁹¹

Host cytokine production in response to *L. pneumophila* infection likely causes most of the acute toxicity of the disease. Cell culture and

animal experiments show that tumor necrosis factor, interferon- γ , and other cytokines are produced during *L. pneumophila* infection.^{14,208} Humans infected with *L. pneumophila* have been shown to produce several cytokines during infection, as well as inflammatory markers such as procalcitonin, neopterin, and C-reactive protein.^{50,75,188}

Episodes of recurrent or relapsing LD in patients with elevated antibody titers support experimental evidence suggesting that the humoral immune system plays a minor role in this disease.⁶⁵ Also supporting this evidence is the rarity of LD case reports in patients with hypogammaglobulinemia or other diseases in which the humoral immune system primarily is deficient. The rise of specific antibody levels does not seem to have any clinical correlates, nor does the absolute antibody level.⁶⁵ Patients may recover from LD without any significant increase in antibody levels, again providing indirect evidence of the limited role of the humoral immune system.

Several studies showed that passive or active immunization is protective against intraperitoneal and subcutaneous chamber infection in rats, mice, and guinea pigs.^{7,68,103,174} Preopsonization of *L. pneumophila* before intratracheal inoculation of hamsters was found to be partially protective, but several investigators showed that active immunization fails to protect against pneumonia after intratracheal, aerosol, or intranasal inoculation of large numbers of *L. pneumophila* bacteria.^{11,55,68} Protective immunity to pulmonary challenge in the guinea pig can be achieved after sublethal infection or infection with an avirulent mutant strain and by vaccination with an *L. pneumophila*-derived metalloprotease or outer membrane protein.^{15,16,18,203}

Evidence for the importance of the cellular immune system in preventing infection largely is indirect and is based on the greater prevalence of LD in immunosuppressed patients with cellular immunodeficiencies.^{65,191} Curiously, LD in patients with acquired immunodeficiency syndrome (AIDS) has been reported infrequently, although one epidemiologic survey showed that patients with AIDS had a disease attack rate approximately 40 times greater than that in the normal population.^{17,18,137,203}

The pathogenesis of Pontiac fever is not understood. No differences have been detected between an *L. pneumophila* strain isolated from an

outbreak of Pontiac fever and strains isolated from outbreaks of LD; these studies have included examination of virulence in an animal model, toxin production, and biochemical characteristics.¹⁹¹ The lack of detailed clinical studies of patients with Pontiac fever makes it difficult to produce an experimental model of this disease. Because Pontiac fever has a short incubation time, which can be as brief as 12 hours, this disease likely does not represent widespread bacterial multiplication within the body and more likely it is a toxin-induced or allergic disease. In fact, the link between *Legionella* and Pontiac fever is circumstantial; entirely possible is that other microbes, or their toxins, coexisting with *Legionella* may cause the disease.^{89,118} The clinical syndromes most like Pontiac fever are bath-water fever, humidifier fever, and extrinsic allergic alveolitis; these syndromes are thought to be caused either by the direct toxic activity of inhaled endotoxin or by an allergic reaction to microorganisms, most particularly amebae such as *Naegleria* spp.^{66,148,177} *L. pneumophila* makes a poorly active endotoxin, a finding suggesting that if inhaled endotoxin is the cause of Pontiac fever, then the endotoxin comes from non-*Legionella* bacteria. Support for inhaled endotoxin as the cause of Pontiac fever is found in two studies of endotoxin present at outbreaks of the disease.^{36,79} Both Pontiac fever and LD have been reported from the same disease outbreaks, thus raising the questions whether Pontiac fever is a very mild form of LD, whether it is caused by non-*Legionella* toxins or bacteria present in the same aerosols, and why some people develop LD and others Pontiac fever.^{4,70,157}

CLINICAL MANIFESTATIONS OF LEGIONNAIRES' DISEASE

Signs and Symptoms

LD usually manifests as pneumonia.⁶⁵ The pneumonia is atypical in that usual pathogenic bacteria generally are not isolated from respiratory tract secretions or blood, and patients do not respond, except fortuitously, to antimicrobial agents commonly used to treat pneumonia in adults (e.g., penicillins, cephalosporins, and aminoglycosides). Beyond this, considerable speculation and controversy continue over whether a distinct clinical syndrome exists. Several prospective studies of both community-acquired and nosocomial LD failed to demonstrate any clinical, radiographic, or nonspecific laboratory features that distinguish LD from other common causes of pneumonia.^{57,74,96} The classic clinical findings are reviewed because many physicians consider that they are distinctive for *Legionella* pneumonias. Whether LD in children mimics the clinical findings in adults is unknown because of the rare instances of well-documented pediatric cases and the possibility of spectrum bias.

The onset of pneumonia may be either insidious or abrupt. Recurrent chills, abdominal pains, myalgia, headache, malaise, anorexia, and severe fatigue are common findings. Diarrhea, consisting of loose, nonbloody stools several times a day, occurs in 30% to 40% of patients. Fever may be low grade or absent initially. Over the course of a day to several days, these nonspecific symptoms gradually worsen, often resulting in severe debilitation. These symptoms gradually increase in severity, as measured by the median time of 4 to 5 days to present for hospital care, at which time the patient can be quite ill. Noteworthy is the frequent absence of symptoms referable to the respiratory system. Rash, splenomegaly, adenopathy, and rhinorrhea are exceptionally uncommon findings. Physical examination early in the illness generally is remarkable for a paucity of localizing findings and the frequent impression that the patient has an influenzal or typhoidal illness.

Within a day to several days after onset, the patient usually, but not always, develops a high fever. Respiratory complaints, especially dyspnea and pleuritic chest pains, may become prominent. Cough usually is not a major complaint, although it is common. The sputum is hardly ever frankly purulent; blood-streaked sputum or frank hemoptysis is observed in 20% to 30% of patients. Many patients experience confusion, cerebellar ataxia, lethargy, agitation, or some other neurologic disorder. Severe abdominal or back pain may occur, sometimes with localization. Physical examination at this time reveals a "toxic" febrile patient with apparent multisystem disease. Chest examination usually discloses findings of consolidating pneumonia. Depending on the location and stage of consolidation, rales may or may not be heard. Pleural friction rubs or signs of pleural effusion can be observed. Despite frequent

symptoms of abdominal pain, signs of peritoneal irritation, such as decreased bowel sounds or rebound tenderness, seldom are detected. Signs of meningeal irritation occur rarely.

Most previously healthy patients recover without specific therapy, usually by day 7 to 10 of illness. Patients with mild disease not requiring hospital admission appear to do quite well without antibiotic therapy.¹⁹⁹ Patients who do not recover usually die of progressive respiratory failure, along with failure of other organ systems. Empyema, pulmonary cavitation, renal failure, memory loss, fatigue, and neurologic disorders all are potential complications and may persist for weeks to months after onset of the disease. Various extrapulmonary diseases may very rarely occur as the result of LD; the most common of these disorders are pancreatitis,¹⁴³ hepatitis, and myopericarditis.^{8,139} Myositis, as measured by elevated serum creatine kinase levels, occurs commonly, with severe muscle disease such as rhabdomyolysis a rare complication.^{117,201} Most of these extrapulmonary diseases improve rapidly with resolution of the pneumonia.

Focal infection without pneumonia is a very rare manifestation of *Legionella* spp. infections, with only a handful of cases reported (Box 137.1). Direct inoculation of bacteria into surgical or traumatic wounds is the usual mode of pathogenesis, although bacteremia and bacteremic metastatic infection have been reported.^{140,168} *Legionella* spp. were implicated by polymerase chain reaction (PCR) testing as a cause of persistent cervical lymphadenitis in children, often after hot tub exposure. Because the involved lymph nodes were stain and culture negative for *Legionella*, and because the patients failed to improve with macrolide therapy, the study needs verification.⁴²

Radiographic Findings

The radiographic hallmark of LD is an acinar filling pattern with consolidation.^{47,65,191} There is no distinctive predilection for any lung region; pleural-based consolidation and bilateral infiltrates may occur. Nodular infiltrates may be seen, as may cavitation in the areas of original consolidation. Purely interstitial infiltrates are distinctly uncommon findings in established disease, but they rarely occur very early in the disease process; these interstitial infiltrates rapidly progress to consolidating infiltrates within a day or so. High-resolution computed tomography of lungs of patients with LD often reveals a mixture of ground-glass opacities and consolidation, and in the convalescent phase an organizing pneumonia pattern may be seen.^{98,210} Pleural effusion, with or without parenchymal infiltrates, is a common finding in chest computed tomography scans and is less commonly visualized in plain films. Pleural effusion has been documented as the only chest finding in patients treated early with specific antibiotic therapy.

Laboratory Findings

Nonspecific abnormal laboratory results are common in patients with LD.^{47,65} Hematologic abnormalities may include leukocytosis or leukopenia, usually with a left shift; lymphopenia; thrombocytosis; and disseminated intravascular coagulation. Proteinuria and pyuria are common findings; myoglobinuria also may be present. Hyponatremia and hypophosphatemia commonly occur, as do elevations of aminotransferase enzymes, bilirubin, alkaline phosphatase, lactate dehydrogenase, and creatine kinase. Elevated ferritin is also seen. Severe azotemia occurs, although rarely. Elevation of cold agglutinin titers, cold agglutinin-induced hemolytic anemia, and elevation of complement fixation titers to *Mycoplasma pneumoniae* may also occur. Arterial oxygenation usually is depressed in relation to the extent of pneumonia.

Laboratory diagnosis of LD is best accomplished by urine antigen testing, but results of this test can be falsely negative. Recovery of *Legionella* from sputum or other lower respiratory tract secretions or tissues requires specialized laboratory testing and is insensitive.⁶⁴ Other specific diagnostic methods are detection of *L. pneumophila* antigen by immunofluorescent microscopy and detection of *Legionella* DNA in respiratory tract specimens by using PCR. Serologic diagnosis is of uncertain value in children, but it is useful in adults.

Sputum is plated on buffered charcoal yeast extract medium supplemented with α -ketoglutaric acid (buffered charcoal yeast extract [BCYE- α]) and on BCYE- α supplemented with antibiotics.⁶⁴ *Legionella* organisms grow on these media 3 to 7 days after inoculation and

incubation at 35°C in air. Culture diagnosis has a higher yield than does immunofluorescent microscopy or serology and yields no false-positive results. Sputum culture yield depends on the severity of illness; it is close to 100% for LD affecting immunocompromised patients and patients with ventilator dependent pneumonia, but can be as low as 10% to 25% in mild LD. Blood and pleural fluid cultures have very low yield, less than 5% to 10%, with blood culture positive only in severely ill, usually immunocompromised, patients.

Immunofluorescent microscopy for *L. pneumophila* is a rapid and highly specific (99.9%), but insensitive (50–70% sensitivity), technique for diagnosis.⁶² It can be performed on sputum or lung tissue in 1 to 2 hours after receipt of the specimen. The test is technically demanding, requiring extensive expertise and training; use of the test by inexperienced technologists yields more false-positive than true-positive findings. Because of these difficulties, few laboratories perform this testing.

Serologic testing is of most value in epidemiologic studies and of least value in the short-term diagnosis of sporadic cases.⁶¹ As many as 25% of patients with culture-documented disease fail to undergo seroconversion against the homologous serotype; this failure is not related solely to early treatment or immunosuppression, although these factors may cause failure of antibody formation. As long as 3 months may be required for antibody levels to increase after onset of illness; the median time is approximately 2 weeks. Moreover, as with any other means of immunologic diagnosis of this disease, the multiplicity of antigenic types renders serologic testing extremely cumbersome. Because between 5% and more than 25% of the normal population have antibody titers as high as 1:512 to *Legionella*, only a fourfold rise in titer is considered significant. The specificity is highest for *L. pneumophila* serogroup 1 and much lower for other species. Commercial testing kits can yield false-positive results, and they may also be insensitive in comparison with reference laboratory tests. Only paired samples, drawn 3 to 6 weeks apart and tested in parallel, should be tested. Specimens taken up to 9 to 12 weeks after onset of the disease should be tested if earlier samples reveal no changes. A negative serologic test result does not exclude disease.

The specificity of seroconversion to *L. pneumophila* serogroup 1 ranges from 95% to 99%.⁶¹ Cross-reactive antibodies may be found in the serum of patients with leptospirosis, melioidosis, *Bacteroides fragilis* infections, *P. aeruginosa* infections, *C. jejuni* enteritis, and possibly *Haemophilus influenzae* or enteric bacterial infections. However, even 99% specificity is not sufficient for certainty of diagnosis of a sporadic case. If the estimated 1% prevalence of LD in children is correct, fewer than 50% of all seroconversions yield truly positive results (positive predictive accuracy of 45%). This observation, combined with the studies cited previously showing age-related elevations of anti-*Legionella* antibody in young asymptomatic children, renders serologic diagnosis of pediatric LD highly suspect.

Detection of soluble bacterial antigen in urine can be used to diagnose *L. pneumophila* serogroup 1 infections successfully, and it is the most sensitive and fastest test for community-acquired LD.^{62,60} The major drawback of this test is that it preferentially detects only *L. pneumophila* serogroup 1 infections. Otherwise, it has an excellent sensitivity (90–99% versus culture and 60–70% in patients with community-acquired LD) and extraordinary specificity (at least 99.9%). The antigen test may be positive when the result of sputum culture for *L. pneumophila* serogroup 1 is negative, especially in previously treated patients and in epidemics of LD. In nosocomial LD and in LD of immunocompromised patients, the antigen test is less sensitive because other serogroups and other *Legionella* spp. become likely in these groups. Although the antigen test detects 60% to 70% of patients with community-acquired LD, fewer than 40% of patients with nosocomial disease test positive. A negative urine antigen test result should not be used as the sole reason to stop therapy for LD.⁵⁶

The PCR test has been used to detect *L. pneumophila* in sputum, serum, and urine. Whereas both sensitive and specific PCR tests are available, none are commercially available in the United States. Several US reference laboratories perform home brew PCR assays. PCR testing appears to add approximately 11% additional yield to that obtained by urine antigen testing.⁵³ In regions where LD caused by *L. longbeachae* is common, such as Australia and New Zealand, PCR testing can be

significantly more sensitive than urine antigen testing.¹⁵² The same can be said of diagnosis of LD in immunosuppressed patients and in patients with nosocomial disease, especially when there is not local expertise with respiratory tract culture for *Legionella* spp.

With the exception of the urine antigen and the PCR test, none of the nonculture tests is as sensitive as is culture diagnosis. Culture should be performed in every case; if desired, the other tests can be used to provide same-day answers. Because none of the *Legionella*-specific tests is 100% sensitive, the clinician sometimes must treat for LD in the absence of confirmatory laboratory tests. One or 2 days of therapy with erythromycin apparently does not affect the sensitivity of the diagnostic tests, although therapy with azithromycin or levofloxacin can affect culture yield. Therapy should not be withheld pending results of laboratory tests.

TREATMENT

No adequately sized prospective clinical studies of antimicrobial therapy for LD have been performed. All recommendations regarding therapy are based on retrospective and small prospective clinical studies in adults, as well as laboratory studies.

Because of the superiority of newer fluoroquinolone agents and azithromycin in experimental nonhuman studies, and in large retrospective studies of these agents in adults with LD, the current recommendation is that adults with severe LD and immunocompromised patients with the disease be given either azithromycin or fluoroquinolone therapy, rather than erythromycin or clarithromycin therapy. In one prospective observational study in adults that compared levofloxacin-treated patients with patients who received the less effective macrolides, erythromycin and clarithromycin, patients who received levofloxacin had a significantly shorter time to defervescence and a shorter length of hospital stay than did patients treated with erythromycin or clarithromycin.¹⁵³ However, other studies have shown no significant differences in outcome for patients treated with clarithromycin or levofloxacin.^{72,95} A retrospective cohort analysis of clinical outcomes in 3152 patients hospitalized for LD showed no significant differences in outcomes between patients treated with either quinolones or azithromycin, including patients with severe disease.⁸⁸ The results of this study were confirmed in another retrospective propensity-adjusted, single-hospital study that also showed that clarithromycin therapy was associated with a longer length of stay.²¹² A recent retrospective study of critically ill French patients showed that fluoroquinolone therapy, as opposed to therapy with a macrolide other than azithromycin, was associated with a lower mortality rate. In addition, this study showed that combination anti-infective therapy was not superior to fluoroquinolone monotherapy.²¹³ Taken together, these three studies provide reasonably strong evidence that either levofloxacin, or another highly active fluoroquinolone, or azithromycin should be used for hospitalized patients, that clarithromycin or erythromycin administration should be avoided in such patients, and that combining a macrolide with a fluoroquinolone for severe disease provides no substantial benefit. Nonhospitalized patients with mild LD can be treated equally well with any of the specific therapies, including doxycycline, newer fluoroquinolones, azithromycin, clarithromycin, or erythromycin.^{58,59,134} No inherent reason, other than age-specific drug toxicity, precludes these guidelines for children.

Fluoroquinolone antimicrobial agents generally are contraindicated in children, although the evidence suggests that the risk for toxicity from short courses of therapy is low. On the basis of minimal, if any, significant differences in outcomes in adults treated with either azithromycin or fluoroquinolones, fluoroquinolone therapy should be reserved for special cases such as drug allergy, potential for cardiac toxicity, availability, and drug interactions.

Clarithromycin (7.5 mg/kg every 12 hours) may be used in place of erythromycin, although good laboratory and reasonable clinical data show that this drug is no more effective for LD than is erythromycin.^{20,162} Clarithromycin is not approved by the US Food and Drug Administration (FDA) for the treatment of LD. Azithromycin has largely replaced erythromycin as the drug of choice for the treatment of LD in children primarily because of the adverse effects associated with erythromycin, especially gastrointestinal effects and severe phlebitis when the drug is given intravenously.

Azithromycin, which is approved for use in children in the United States, is as active against *Legionella* bacteria as are the newer fluoroquinolone agents, thus making it a candidate for the drug of choice for severe pediatric LD or for LD in immunocompromised children. The drug dose for children for this type of pneumonia has not been studied, but on the basis of extrapolation from adults, a dose of 10 mg/kg (maximum, 500 mg) given once daily for 3 to 5 days should be sufficient in most cases, with extended duration of therapy (7–10 days) for severely immunocompromised patients. Azithromycin is available in both intravenous and oral forms and is approved by the FDA for use in adults with LD. All macrolide/azalide antimicrobial agents, including azithromycin, have the potential for causing QT prolongation. Two studies of deaths resulting from cardiovascular causes in adults who were administered azithromycin gave diametrically opposed results. One study showed that azithromycin was associated with a higher death rate than in patients given amoxicillin, but not levofloxacin, particularly when the patients had significant risk factors for cardiovascular disease.¹⁷⁰ The other study showed that patients without a high risk of cardiovascular disease had no increased death risk with azithromycin when compared with the risk of penicillin administration, a finding suggesting that infection by itself increases the risk of death from cardiovascular causes.¹⁸⁷ A study of pneumonia mortality rates in 74,000 adults showed that those patients receiving azithromycin had lower mortality rates than did patients receiving other antimicrobial agents, although a slight increase in myocardial infarctions was reported in azithromycin-treated patients.¹⁴⁷ Patients with risk factors for cardiac arrhythmias are probably at somewhat increased risk for heart block when they are given macrolides/azalides, as well as fluoroquinolone antimicrobial agents, but the risk is relatively low.¹³¹

Newer fluoroquinolone agents, along with azithromycin, are considered to be the drugs of choice for the treatment of severe LD in adults. Levofloxacin is used commonly in the United States to treat this disease, in a dosage of 500 to 750 mg daily for 10 to 14 days. No dosage guidelines exist for the treatment of pediatric LD because of the potential for drug toxicity in this population. Levofloxacin is the only available quinolone agent approved by the FDA for the treatment of LD in adults; neither ciprofloxacin nor moxifloxacin is approved for this indication. Ciprofloxacin appears to be effective for this indication on the basis of case reports, and moxifloxacin may be effective on the basis of limited laboratory studies and case reports.⁸⁶ Combining a macrolide with a fluoroquinolone has been reported to be no more effective than a fluoroquinolone alone.²¹³

Alternative drugs to macrolides or quinolones include doxycycline and possibly cotrimoxazole. Neither of these agents has been approved for this use by the FDA, although limited clinical and experimental data support their effectiveness, more for doxycycline than for cotrimoxazole. Cotrimoxazole should be used only if there is no possibility of using a macrolide, tetracycline, or fluoroquinolone drug because of the lack of clinical reports of its successful use for the treatment of LD. Doxycycline, because of its high lipid solubility, may be more effective than is tetracycline, although whether this is true remains conjecture. The dosage of doxycycline used in children is 2 to 4 mg/kg per day, given in one or two doses. The use of tetracyclines is associated with the risk for dental staining in children younger than 8 years of age. The daily cotrimoxazole dosage is 15 to 20 mg/kg of the trimethoprim component and 75 to 100 mg/kg of the sulfamethoxazole component in three divided doses; cotrimoxazole use in newborns may cause kernicterus. The duration of therapy for these drugs is the same as that for erythromycin.

Rifampin therapy for LD is not recommended, whether the drug is given by itself or in combination with another agent. The use of this drug for treatment of LD is not approved by the FDA. A small, non-randomized study showed that adult patients treated with combination rifampin and clarithromycin had significantly longer hospital lengths of stay than did patients treated with clarithromycin alone, with a trend to worse outcome in other outcome measures in those patients given combined therapy.⁹² Rifampin therapy induces the metabolism of macrolides for many weeks, so that when rifampin therapy is stopped, macrolide serum and lung levels will be quite low.^{166,200} No good clinical or laboratory evidence indicates that combining rifampin with either azithromycin or a fluoroquinolone is beneficial.

Treatment of extrapulmonary foci of infection does not appear to differ from treatment of LD without extrapulmonary disease. The duration of therapy and indications for surgical drainage need to be assessed individually in these cases.

Response to Treatment

Most patients improve dramatically within a few days after initiation of specific therapy.^{47,57,65,191} Response may be as rapid as 6 hours after administration of the first dose of therapy. Patients regain their appetite, lose symptoms of myalgia and fatigue, and feel better overall within a few days. Up to a week may be required for a patient to become completely afebrile, with longer periods sometimes required for severely immunosuppressed patients. The chest radiograph changes slowly and even may appear to worsen despite overall clinical improvement; progressive consolidation after 3 to 4 days of antimicrobial therapy is unusual. Because very severe immunocompromise can impair the ability of the cellular immune system to clear infection completely, some of these patients are prone to relapses of disease once antimicrobial therapy has been stopped, even after a long course of therapy.^{97,180} The relapses can be insidious and manifest only with renewed immunosuppression. Profoundly immunosuppressed patients with LD who do not have recovery of immune function may benefit from prolonged suppressive antimicrobial therapy until they recover sufficient cellular immune function.

Failure to respond to appropriate therapy can result from severe underlying disease, advanced pneumonia at presentation, coinfection with another microorganism, mistaken diagnosis, and complications of pneumonia. These complications can include pulmonary embolism, empyema, pancreatitis, myopericarditis, hepatitis, and soft tissue infections.

The mortality rate in otherwise healthy adults who are treated promptly is approximately 5%, whereas in treated immunosuppressed patients it is approximately 20%. Untreated fatality rates range from 15% to 20% in normally healthy patients and upward of 80% in immunosuppressed patients. However, very mild community-acquired LD in healthy adults who do not require hospitalization appears to have a negligible mortality risk, and patients may not require specific antibiotic therapy, although such a course may not be advisable.¹⁹⁹ Even in previously healthy patients, delayed therapy and development of respiratory failure are exceptionally poor prognostic factors.^{71,160,193}

DIFFERENTIAL DIAGNOSIS

Other causes of atypical, or culture-negative, pneumonia may closely resemble LD. Mycoplasma pneumonia usually is a milder illness not requiring hospitalization. Cough is a prominent symptom in mycoplasma pneumonia, whereas it is not in LD. Neither rash nor otitis is found in LD, nor is postpneumonia reactive airways disease. Laboratory abnormalities also are found more commonly in LD. Serologic testing may provide positive results for both diseases, a confusing finding that can be clarified by performing specific laboratory testing. Fortunately the treatment is the same for both diseases.

Psittacosis and Q fever may closely resemble LD. A history of bird or cattle exposure may be helpful, but the absence of such exposure does not exclude either of these zoonoses. An interstitial rather than an acinar-filling infiltrate on chest radiograph would be a point against LD. Pathogen-specific laboratory tests help in this differential diagnosis. A tetracycline can be used successfully for all three of these diseases.

Early in their evolution, some diseases may resemble LD. They include typhoid fever, acute coccidioidomycosis, influenza, the typhus or spotted fevers, and leptospirosis. Distinguishing these diseases on the basis of their clinical evolution, the laboratory results, and the exposure or travel history generally is easy.

Tularemia may pose a problem in the differential diagnosis because immunologic test results for LD can be falsely positive in tularemia and because some of the growth characteristics of *Francisella tularensis* closely resemble those of *Legionella*. In regions endemic for tularemia, clinicians must work closely with the laboratory to facilitate this differential diagnosis. One case record of tularemia misdiagnosed as LD reported that the patient responded to erythromycin therapy.

Dual infection sometimes occurs in LD. Coexistence of LD with pneumonia caused by *Mycobacterium tuberculosis*, pneumococcus, *H. influenzae*, *Neisseria meningitidis*, *Pneumocystis jiroveci*, *Moraxella catarrhalis*, and various viral agents has been reported. Thus dual infection should be suspected in patients not responding to therapy for LD. Pathogen-specific laboratory tests often are useful in these cases.

CLINICAL SYNDROMES CAUSED BY OTHER *LEGIONELLA* SPECIES

Relatively few cases have been reported of disease caused by the non-*L. pneumophila* *Legionella* spp., with the major exception of *L. longbeachae*.^{5,73,206} These reported cases have few differences in clinical findings, diagnostic methods, or treatment. Almost all cases of LD caused by *Legionella* spp. other than *L. pneumophila* or *L. longbeachae* have been reported to occur in immunocompromised patients, and because of these patients' underlying diseases and immunocompromise, the pneumonia severity and rapidity of response to therapy may be compromised. Disease caused by *L. longbeachae* appears to very similar to that caused by *L. pneumophila* in terms of clinical findings and response to therapy.²¹⁴ The lower frequency of these infections in normal hosts most likely reflects the decreased virulence of the bacteria. *L. longbeachae* has a different mechanism of transmission than does *L. pneumophila* because *L. longbeachae* infections do not appear to be transmitted from water sources, but rather from nonsterile potting soil.^{30,120,184} Exposure to potting soil that has been exposed to high ambient temperatures, not washing hands after using the soil, and cigarette smoking are the major risk factors for this disease. The mode of spread and nosocomial reservoirs of the *Legionella* spp. other than *L. pneumophila* and *L. longbeachae* are not well defined. These infections are unlikely to be diagnosed by immunologic means, except for *L. longbeachae* infection in endemic regions (Australia and New Zealand) because few laboratories routinely test for all possible species. Laboratory testing by culture is the preferred test for all these non-*L. pneumophila* species, although genus- and species-specific PCR testing may also have good yield.^{12,152} As with *L. pneumophila*, and even more so for the non-*L. pneumophila* *Legionella* spp., treatment sometimes must be based solely on clinical suspicion without the benefit of confirmatory laboratory tests.

PONTIAC FEVER

Clinical Manifestations

Fever, myalgia, malaise, chills, and headache are the most common symptoms of Pontiac fever.⁸⁹ The symptoms may begin suddenly or may have a more gradual onset for several hours. Many symptoms are respiratory, such as dry and nonproductive cough, chest pain, and pharyngitis. Nausea is a common manifestation, but diarrhea and vomiting are less frequent. Neurologic symptoms including dizziness, confusion, and poor coordination also have been reported. Pontiac fever symptoms usually are at their worst within a day after the onset of illness and gradually resolve over a 2- to 7-day period. Physical examination shows only tachycardia and fever. Leukocytosis has been the only laboratory abnormality reported. Chest radiographs show no abnormalities. Pulmonary function testing has not been performed in patients with Pontiac fever. Rechallenge by return to the contaminated building in the original Pontiac outbreak produced only a mild illness compared with first exposure; the length of time between first and second exposures was not stated clearly.

Diagnosis

The diagnosis of Pontiac fever primarily is one of exclusion.^{47,191} Significant rises in anti-*Legionella* antibody level, combined with characteristic symptoms and isolation of *Legionella* from an aerosol source, are the diagnostic criteria. Rarely, *L. pneumophila* urinary antigen may be detected.⁶³ Detailed epidemiologic and environmental studies must be performed to diagnose Pontiac fever specifically because of the nonspecificity of the symptoms and the ubiquitous presence of environmental *Legionella*. Definitive diagnosis of sporadic cases is difficult.

Treatment

Antimicrobial therapy is not effective for the treatment of Pontiac fever. Removal of the patient from the area of the contaminated water source and symptomatic therapy as needed are the best means of management.

Acknowledgment

William Mason provided excellent suggestions for improvements in the manuscript.

Rat-bite fever is an acute febrile illness usually acquired by humans from the bite of a rat. The disease may be caused by two different bacteria both known to colonize rats. Although both *Streptobacillus moniliformis* and *Spirillum minus* are causative agents of rat-bite fever, these organisms have different epidemiology, incubation periods, and clinical presentation. *S. moniliformis* accounts for most cases of rat-bite fever reported in published reports and is the focus of this chapter. *S. minus*, reportedly more common in Asia, is discussed in Chapter 143.

Rat-bite fever caused by *Streptobacillus* is typically characterized by fever, rash, and arthritis. Although it is frequently attributed to the bite of a rat, other animals may be infected, and modes of transmission other than a bite have been documented. Haverhill fever, for example, is acquired after ingestion of contaminated food or water. *S. moniliformis* is a zoonosis with worldwide distribution,^{50,141} and it is the leading cause of rat-bite fever in the United States.

HISTORY

The first description of rat-bite fever is found in the 2500-year-old Indian *Compendium of Medicine*, the *Susruta Samhita*.²⁶ In this text, a description of the illness is given that remains valid today: “The blood of any part of the human body coming in contact with the semen of rats or scratched with their nails or teeth is vitiated and gives rise to the appearance of nodes, swellings, eruptions of circular erythematous patches on skin, pustules, violent and acute erysipelas, breaking pain in the joints, extreme pain in the body, fever, anemia, aversion to food, shivering, and horripilation.” The disease also was known in ancient Japan, where treatment consisted of the local application of herbs and dynamite to cause an “explosion in the wound.”²⁶

The first modern accounts of the disease are found in a lecture by Professor Eli Ives at Yale University in 1831.⁴⁷ In 1900, Miyake⁸³ gave a detailed description of the disease, which he named *sodoku*, from the Japanese *so* (“rat”) and *doku* (“poison”). The first case report was published in 1839.¹³⁸ Schottmüller,¹¹⁷ Blake,¹³ and Levaditi and colleagues⁶⁸ were the first to isolate and describe the causative agent of streptobacillary rat-bite fever in 1914, 1916, and 1925, respectively. The organism has been known as *Streptothrix muris ratti* and *Streptobacillus muris minus* but currently is referred to as *S. moniliformis*.⁵⁹

EPIDEMIOLOGY

Rats are estimated to compose one-third of the mammalian population of the world, with numbers of approximately 10 billion.⁵⁰ More than 2 million animal bites are reported annually in the United States, and rat bites account for a small number (<1%), although the incidence is probably underreported.^{38,50,53} A review of animal bites in Maryland during a 3-year period found that approximately 4.7% were caused by rats or lagomorphs.³² According to another report, 40,000 rat bites are reported annually.²⁷ Among bitten patients, the risk for rat-bite fever developing is significant, with reported rates between 4% and 11%.^{102,137}

Between 10% and 100% of laboratory rats and between 50% and 100% of wild rats carry *S. moniliformis* as normal nasopharyngeal flora and excrete it in their urine.^{5,50,126} The disease also has been transmitted to humans from mice,¹⁰⁰ squirrels,⁸¹ weasels,³⁴ gerbils,¹³⁹ and rat-eating carnivores such as cats,^{52,82} dogs,^{90,103} and pigs.¹³⁶ In addition, *S. moniliformis* can cause disease in turkeys,⁸⁴ guinea pigs,⁶⁵ koalas,¹¹¹ spinifex hopping mice,⁶¹ and nonhuman primates (rhesus monkey).¹³⁰ In one study looking at colonization in dogs with confirmed rat contact, 3 of 10 animals had evidence of *S. moniliformis* by polymerase chain reaction (PCR) using mouth swabs.¹⁴⁰ Because many of these animals prey on rodents, they could pose a potential source of infection for humans.

Children living in crowded urban centers or rural impoverished areas have traditionally thought to be at the highest risk.^{32,60,99,133} However, given the changing perception of rats as family pets, rat-bite fever in the United States is shifting from a disease of poverty to a disease of pet owners, particularly children.^{33,87} Children are generally reported to account for at least 50% of rat-bite fever cases, and indeed, one-half of all *S. moniliformis* isolates identified at the California state Microbial Diseases Laboratory between 1970 and 1998 involved children younger than 9 years of age.⁵⁶ A 2014 *Morbidity and Mortality Weekly Report* review of 17 cases showed a median age of 10 years.¹

In addition, over the last few years in the United States, most cases are now reported among pet owners. To demonstrate the changing epidemiology, a 2007 review of 65 cases going back as far as 1938 showed 26 patients (40%) with wild rat exposure, eight (12%) with laboratory rat exposure, and three (5%) with pet shop rat exposure. Twenty-two (34%) of the patients described an exposure not relating to a bite or a rat.⁴⁰ However, among 11 US cases published since 2012, 10 were associated with pet rats.^{1,11,16,19,43,66,69,71,134,142} Moreover, a review of 17 cases in San Diego from 2010 to 2012 demonstrated that 94% of cases were associated with pets. Although 44% of the patients in this cases series reported having handled a rat, only 38% reported being bitten.¹ An estimated 0.1% of US households owned one or more pet rats during 2011.¹ Some authors have related this figure to the increasing popularity of rats as pets driven by popular culture.^{134,142}

Pet owners include those who keep rats, as pets as well as those who keep rats to feed other pets, such as snakes and large reptiles.^{5,8,30,43,66,69,70,131} Some cases of rat-bite fever have involved laboratory personnel who handle rats.^{1,7} Although rat-bite fever is often reported after the bite of a rat, it also may be transmitted by rat scratches, contact with a break in the skin, mucosal contact (kissing a rat), or simply handling an animal.^{21,30,45,58,96,112}

Rat-bite fever has been reported worldwide; however, it is not a reportable disease. The actual incidence is unknown, although it is widely believed to be underreported. A report from the California state Microbial Disease Laboratory from 2001 reported an incidence of approximately 1.5 cases per year from 1970 to 1998, with more than one-half of the reported cases occurring after 1990. The report cited a possible increase in incidence after 1990; however, this is largely speculative because the numbers represent only confirmed cases.⁵⁶ Difficulty in isolating the organism, improved detection techniques, and an increase in physicians' awareness of the disease all may influence the reported rates. The mortality rate of rat-bite fever has been reported to be 7% to 13% if the disease is left untreated^{33,40,50}; however, the number of patients with mild or subclinical disease is not known.

BACTERIOLOGY

S. moniliformis is a pleomorphic, microaerophilic, nonmotile, nonencapsulated, non-acid-fast, gram-negative bacillus. It measures 1 to 5 μm in length.⁵⁹ The organism is oxidase and catalase negative and ferments glucose, maltose, fructose, galactose, and salicin.⁵⁹ *S. moniliformis* is facultatively anaerobic,^{44,50} and it is the only species in its genus.

The organism is fastidious and requires special handling for isolation. Optimal growth is achieved in trypticase soy agar or broth supplemented with 20% horse or rabbit serum.⁸⁹ Alternatively, brain-heart infusion broth supplemented with “Panmede” (a papain digest of ox liver) also has been shown to support the growth of *S. moniliformis*.¹²¹ Sodium polyanethol sulfonate, which is added to most aerobic blood culture bottles at a concentration of 0.05%, inhibits the growth of *S. moniliformis* at concentrations as low as 0.0125%.¹²¹ Blood culture bottles without sodium polyanethol sulfonate added should be used for primary isolation

of *S. moniliformis* when rat-bite fever is suspected. Another option is to inoculate twice the amount of blood than recommended by the manufacturer into the blood culture bottle.⁵¹ Anaerobic cultures may be more likely to yield the organism.²⁹ Material from lymph nodes, abscesses, and synovial fluid also may be useful material for isolation of the organism.⁵¹ One other alternative is to inoculate citrated blood directly into broth. Cultures should be incubated at 35° to 37°C (95°F–98.6°F) in a humid environment with a partial pressure of carbon dioxide between 8% and 10%.

The morphologic characteristics of the bacterium depend on the environment.⁸⁷ In favorable media, the typical appearance is that of short rods that may grow in chains. In other conditions, the organism tends to grow in long, interwoven filaments that commonly contain beaded and fusiform swellings throughout their length. The Latin term *moniliformis* translates to “in the form of a necklace.” In broth culture, colonies usually appear in 2 to 10 days.⁵⁹ The colonies are white, soft “puffballs” measuring 1 to 2 mm in diameter.⁵ On blood agar plates, the colonies are round, gray, and glistening and measure 1 to 2 mm in diameter after 2 to 3 days of incubation.⁵⁹

Stable L forms of the organism develop spontaneously in vivo or in vitro. These cell wall–deficient forms have a “fried egg” appearance with dark centers and lacy edges when they are grown on solid media.^{59,92} The L form is considered nonpathogenic, even though spontaneous conversion between the two forms has been reported in vitro and may be responsible for relapses and resistance to therapy, although this is not certain.^{40,49,119} L forms are resistant to penicillin and other antibiotics active against the bacterial cell wall. These variants may be deposited in tissues and prolong the symptoms of illness.³⁶

CLINICAL MANIFESTATIONS

Streptobacillary rat-bite fever often has an incubation period of less than a week, usually ranging from 3 to 10 days, although an incubation period of up to 3 weeks has been documented.⁴ Young children may have shorter incubation times. Typically the bite or scratch site, if known, is well healed (as opposed to spirillary rat-bite fever) and often is not evident on examination. Most patients have evidence of contact with a rat, often as a pet, although not necessarily a bite history. Up to 30% or more of patients are reported to have no history of a bite or scratch.²²

A review of 65 patients showed an age range of 2 months to 87 years. Symptoms described included fever (92%), polyarthralgias (66%), rash (61%), nausea and vomiting (40%), headache (34%), myalgias (29%), and sore throat (17%). White blood cell counts were often normal, with polymorphonuclear cell and band form predominance. Only 5 patients (8%) demonstrated white blood cell counts higher than 15,000/mm.^{4,40} Hypertension is also reported.^{19,70}

Rash develops usually within a few days of fever onset (range, 1–8 days) in approximately 75% of patients. The rash may be generalized, but more often it is prominent on the extremities and frequently involves the palms and soles (Fig. 138.1).^{2,30,77,92} The characteristics of the rash are variable, and the rash has been described as maculopapular, petechial, purpuric, pustular, hemorrhagic, vesicular, and bullous.^{4,11,31,40,50,62,66} Desquamation is reported in approximately 20% of patients, and the rash may take several weeks to resolve.⁵⁰

Arthralgia or arthritis with or without joint effusion also develops in more than 50% of patients, classically within the first week of illness. Arthritis usually involves large joints but also may affect small joints, and it tends to be migratory, nonsymmetric, and extremely painful.^{7,45,60,118} Arthritis may be monoarthritic or polyarticular and acute or subacute. Although multiple joints are usually affected, at least two cases of monoarthritic involvement in children have been described involving the hip joint.^{37,57} With untreated infection, persistent or recurrent episodes of fever and arthritis may be experienced.^{46,128}

The arthritis from rat-bite fever is often nonsuppurative with sterile joint fluid cultures. Investigators have hypothesized that *Streptobacillus* may cause both direct infective arthritis and an immune-mediated phenomenon, although this is not well understood.³³ At least two reviews of septic arthritis caused by *S. moniliformis* (defined by isolation from joint or synovial fluid) with at least 17 individual cases have been reported.^{33,135} Rash was present in a minority of patients only. Arthritis

FIG. 138.1 An 8-year-old child with fever, rash, and arthritis with confirmed rat-bite fever from contact with a pet rat. (Courtesy S. Islam, A. Petru, and A. LaBeaud, Children's Hospital and Research Center, Oakland, CA.)

may manifest as a septic hip in children and may mimic rheumatoid arthritis in older patients with peripheral joints affected.^{67,86} Patients with underlying osteoarthritis may be predisposed to this complication. *Streptobacillus* has also been reported as a cause of culture-negative arthritis in patients with human immunodeficiency virus infection.²⁴ The prognosis is quite favorable overall, with all patients in these series recovering with treatment.^{33,135}

Complications of *S. moniliformis* infection include anemia,¹⁰⁶ cutaneous or subcutaneous abscess formation,^{20,57,92,132} interstitial pneumonia,^{79,119} mastoiditis,⁹³ meningitis,^{8,119} pericardial effusion,¹⁸ pancreatitis, prostatitis,¹⁴¹ septic arthritis,^{33,58,73,109,113,135} and overwhelming sepsis.^{1,22,88,119} Children presenting with sepsis may not have rash or typical findings.^{1,22,119} Abscess formation in several different organs, including the brain,³⁵ the female genital tract,⁹² and the spleen,²⁵ has been reported. Unusual and potentially devastating complications include chorioamnionitis,⁴¹ periarteritis nodosa,⁹⁸ and endocarditis. Rapid acute kidney injury has also been described¹⁹ as well as osteomyelitis (first reported in a toddler in 2013).⁴³ Vertebral osteomyelitis¹¹⁴ and vertebral spondylodiskitis⁸⁶ have also been reported in adults.

The most frequent serious complication is bacterial endocarditis, with a nearly 50% mortality rate.^{9,23,77,101,104,110,124} At least 25 cases of endocarditis have been reported in publications, with more than one-half of the cases reported before 1968.^{23,40,42,72,74,110,123} Many patients reported had underlying valvular disease.⁴⁰ In a review of 17 cases, the majority of patients (12) had systemic symptoms, including fever, rash, and arthritis.¹¹⁰ Of 14 cases in which patients' clinical symptoms were reported, murmur was noted in 100%, petechiae in 13%, Osler's nodes in 13%, hepatosplenomegaly in 33%, anemia in 33%, and cardiac dysrhythmia in 13%.¹¹⁰ At least six cases have involved children younger than 18 years of age, with the youngest just 2 months of age.^{79,97,107,110,119,124,127} Of the six children, five died during the acute illness. The three most recent reported cases of endocarditis were reported from Spain in 2010, India in 2013, and the United Kingdom in 2014, all involving adults with native mitral valve endocarditis.^{42,72,74}

At least eight fatal pediatric cases have been reported, the majority with endocarditis. Most deaths were described in the 1930s and 1940s among older children with endocarditis. In the 1980s, two separate cases of infant deaths related to rat-bite fever were described. One case involved a 3-month-old infant with endocarditis, and the other was a 2-month-old infant with disseminated disease. In 2011, another fatal case in a 14-month-old infant with disseminated disease was described, with autopsy findings similar to those of the 2-month-old infant, including interstitial pneumonitis, meningitis (with isolation of the organism from cerebrospinal fluid [CSF]), and hepatomegaly.^{10,59,87,106} In 2013, a 10-year-old previously healthy child with pet rats died after

a 2-day history of fever and nonspecific symptoms. He initially experienced rigors, fevers, vomiting, headaches, and leg pains, and the disorder was misdiagnosed as gastroenteritis. The child collapsed and became unresponsive over the next 24 hours; he had evidence of disseminated intravascular coagulation on autopsy.¹

Haverhill Fever

Unlike typical rat-bite fever, Haverhill fever is transmitted by the ingestion of food or water contaminated by rats, with previous outbreaks involving unpasteurized milk, ice cream (made from raw milk), and water.^{78,94} Haverhill fever was reported first in 1926 after an outbreak of epidemic illness in Haverhill, Massachusetts. In that outbreak, 86 cases developed and were traced to contaminated, unpasteurized milk.⁹⁴ The illness was referred to as *erythema arthriticum epidemicum*. Although this was the first published outbreak, in 1925 approximately 400 cases of a similar illness were reported in Chester, Pennsylvania.⁴⁰ The causative organism was isolated, described in detail by Parker and Hudson⁸⁹ in 1926, and given the name *Haverhillia multiformis*. It was later shown to be identical to *S. moniliformis*. The first outbreak in Britain was described in 1983 at a boarding school in Essex and affected more than 200 students; it was also believed to be related to contaminated raw milk.^{91,122} Haverhill fever is similar to streptobacillary rat-bite fever, with an abrupt onset of fever and chills (100%), rash (95%), and arthritis (97%).^{3,78} Generally, the incubation period is 1 to 3 days. Upper respiratory and gastrointestinal problems are common. Multiple recurrences of fever are found rarely, and the rash tends to be small and uniform in size.⁷⁹

PATHOPHYSIOLOGY AND PATHOLOGY

Factors influencing the virulence of *S. moniliformis* are not well described. The organism has an affinity for synovial tissue in both animals and humans, but the mechanisms by which *S. moniliformis* produces arthritis are unknown.^{54,55,60,63,73,115,129} Studies performed in mice indicate that *S. moniliformis* is only slightly immunogenic and produces mild leukocytosis and minimal homologous antibody production.^{115,116} In addition, the organism is resistant to phagocytic destruction.¹¹⁵ These factors may allow chronic infection to develop. Because the organism may spontaneously convert to the cell wall-deficient form (or L form), this has been speculated to be responsible for relapsing disease.

The pathologic features of streptobacillary rat-bite fever have been described in a limited number of autopsy reports. Common features include ulcerative endocarditis with secondary septic embolization in the liver and spleen, septic arthritis, and interstitial pneumonia.^{13,119} Mononuclear meningitis and erythrophagocytosis also have been reported.¹¹⁹ In a pediatric autopsy report, in which *Streptobacillus* grew from the cerebrospinal fluid, mild flattening of the cerebral gyri with mild collapse of the ventricular system was seen, but no major histopathologic changes were noted in the brain. The kidneys had findings consistent with disseminated intravascular coagulopathy. The small and large intestine, liver, thymus, thyroid gland, larynx, and heart showed mild to moderate autolysis, but no other major histopathologic changes.¹⁰ In most reports, the site of the bite reveals little histologic evidence of inflammation.⁷⁹

DIAGNOSIS

Three fatal cases reported in the Centers for Disease Control and Prevention (CDC) *Morbidity and Mortality Weekly Report* highlight the importance of considering rat-bite fever in the differential diagnosis.^{1,22} The diagnosis of rat-bite fever requires a high index of suspicion on the part of the physician. The diagnosis is suggested in a febrile patient with a history of exposure to rats, but in most clinical settings, the exposure history is not elucidated until after the diagnosis is made. This diagnosis should be considered in patients who present with fever, rash, and arthritis.¹²⁵

Nonspecific laboratory findings may include the following: elevation in the white blood cell count,¹³ usually in the range of 10,000 to 30,000 cells/mm³ with a left shift; mild anemia; and a false-positive serologic test result for syphilis, which may occur in 25% of patients.¹⁰⁶ Direct visualization of the organism on Giemsa stain of blood or joint fluid

may suggest the diagnosis. Serologic assays are not currently available for humans. An enzyme-linked immunosorbent assay has been developed to monitor infection in rodent colonies.¹⁴

Molecular techniques may be an effective means for detection of *S. moniliformis* from humans and animals and may offer an alternative to traditional culture methods.^{6,12,15,47} Broad-range PCR amplification of a part of the 16S rRNA gene followed by sequencing allowed the detection and identification of *S. moniliformis* in blister fluid of a patient reported in 1991.¹² A PCR assay specific for *S. moniliformis* was described by Boot and colleagues¹⁵ by using primers designed on the basis of 16S rRNA gene base sequence data of human and rodent strains of *S. moniliformis*, and similar assays have been used subsequently.^{85,140} PCR testing is becoming more refined; a 2008 publication described new primers to amplify the 16S rRNA gene of *Streptobacillus* spp. more specifically than prior tests.⁶⁴ Since 2008 multiple reports have noted detection of *S. moniliformis* by PCR from blood, bite wounds, and synovial fluid.^{17,19,24,31,43,71,85} Although PCR testing using 16S rRNA is becoming more readily available through tertiary care centers and reference laboratories, it is still not widely used in the community hospital setting.¹⁹

S. moniliformis has been cultured from blood, joint fluid, abscesses, pericardial fluid, meninges, and tissues obtained at autopsy.^{10,21} The organism has strict growth requirements, and the choice of culture media and technique is of critical importance for optimal growth of the bacterium (see the earlier discussion of bacteriology). Whenever this agent is suspected, it is helpful to alert the laboratory that will be performing isolation. In general, routine aerobic blood cultures are not satisfactory for isolation. If the organism is isolated, it may be identified rapidly by gas-liquid chromatography. *S. moniliformis* has a characteristic fatty acid profile, with major peaks of palmitic, linoleic, oleic, and stearic acid.^{92,108} Electrophoretic protein patterns also have been described that can distinguish Haverhill fever strains from rat-bite fever strains.²⁸

The differential diagnosis for streptobacillary rat-bite fever includes illness caused by *S. minus* (see Chapter 142). It also includes all relapsing fevers, such as *Borrelia recurrentis* infection, malaria, and typhoid. Rocky Mountain spotted fever must be considered⁷⁶ as well as other infectious entities, including leptospirosis, Lyme disease, disseminated gonococcal infection, meningococemia, brucellosis, and syphilis. Viral infections also may be mistaken for rat-bite fever. Acute rheumatic fever should be considered as well. The frequent symmetric involvement of small joints of the hands can be particularly suggestive of rheumatoid arthritis.⁶⁰ Other noninfectious entities include drug reactions, collagen vascular disease, and other rheumatologic conditions. With the emergence of outbreaks of Coxsackievirus A6 in the United States as recently as 2011, clinicians must also be wary of misdiagnosing rat-bite fever as atypical hand, foot, mouth disease.^{43,75}

TREATMENT AND PREVENTION

Although fatal in some cases, streptobacillary rat-bite fever is a very treatable disease that is usually responsive to a variety of antibiotics. The treatment of choice for *S. moniliformis* is penicillin G. Either procaine penicillin intramuscularly or aqueous penicillin intravenously is acceptable.^{4,98} Tests of *S. moniliformis* antibiotic susceptibility usually demonstrate sensitivity to penicillins, cephalosporins, carbapenems, aztreonam, clindamycin, tetracyclines, and vancomycin; intermediate susceptibility to aminoglycosides, fluoroquinolones, amikacin, and chloramphenicol; and resistance to trimethoprim-sulfamethoxazole.^{39,141} Only one penicillin-resistant *S. moniliformis* strain has been demonstrated, and that was more than 50 years ago.⁴⁰ A 1965 study noted the rapid response to penicillin was in stark contrast to other regimens.⁹⁸ Penicillin is also the drug of choice for Haverhill fever; however, Haverhill fever has also been successfully treated with tetracycline.¹²¹

Traditionally in adults, the dosage of penicillin has been recommended at no less than 400,000 to 600,000 IU/day of intravenous aqueous penicillin G continued for at least 7 days and up to 10 to 14 days.^{40,48,62,87,104} Treatment with penicillin for up to 28 days or more has been reported in cases of presumed septic arthritis and osteomyelitis.^{43,135} If no response is seen within 2 days, the dosage should be increased to 1.2 million IU/day.⁹⁸ Children have been treated successfully with 20,000 to 50,000 IU/

kg/day of intravenous penicillin, up to a maximum of 1.2 million IU/day.¹²⁰ In children, some investigators suggest that after 5 to 7 days of intravenous therapy with goal response, treatment may be completed by oral penicillin.^{22,40,62}

No controlled studies have been conducted on the duration of intravenous versus oral therapy, and increasingly more patients are being treated with shorter durations of intravenous therapy. Case reports have shown success with as little as 48 to 72 hours or less of intravenous therapy in patients without severe disease.^{80,105,134} Both adults and children have also been treated successfully as outpatients with regimens including oral penicillin, amoxicillin, cephalexin, clarithromycin, and doxycycline (in the case of penicillin-allergic patients).^{21,31,69,70,131,142} Oral penicillin VK, 1 to 2 g/day in divided doses, may be given.^{48,120} Other successful regimens have included aminoglycosides, cephalosporins, chloramphenicol, and gentamicin.^{19,21,30,58,95,104,110,118} The suggested dose is oral tetracycline, 500 mg four times per day, or intramuscular streptomycin, 7.5 mg/kg twice daily.⁹⁴ Treatment failure with oral erythromycin has been reported.⁵⁷

Optimal therapy for *S. moniliformis* endocarditis is based on case reports, given the rarity of disease. High-dose aqueous intravenous penicillin G or procaine penicillin intramuscularly is the treatment of choice. Some experts suggest using penicillin in combination with streptomycin or gentamicin for up to 2 weeks, although data are limited.^{40,72} For adults, daily administration of intramuscular procaine penicillin G at 4.8 million IU has been recommended if the isolate is susceptible (0.1 µg/mL).^{40,110} If the isolate is more resistant, intravenous penicillin G at 20 million IU/day should be used.¹¹⁰ In children, the dosage is intravenous aqueous penicillin, 160,000 to 240,000 IU/kg/day (96–144 mg/kg per day), up to the adult maximum of 20 million IU/day.^{40,110,120} Treatment should be continued for at least 4 weeks up to 6 weeks on the basis of treatment of other types of bacterial endocarditis.⁴⁰ Successful treatment of endocarditis with ceftriaxone in combination with gentamicin has been reported.¹⁰⁴ In a review of 16 patients with endocarditis, four patients who did not receive specific antimicrobial therapy died, as did three patients who received less than 1 million IU/day of penicillin; only two patients who received more than 1 million IU/day of penicillin died, and one of those patients died suddenly 4 months after valve replacement.¹¹⁰ Although endocarditis is more common in patients with artificial valves, the three most recently reported published cases since 2010 all had native valve endocarditis.^{42,72,74}

PREVENTION

Rat-bite fever can be prevented by controlling rodents in urban areas, properly handling rodents including pets, and avoiding unpasteurized milk products. Persons who own rats and those who work with rodents should receive anticipatory guidance regarding the handling of these animals and the signs and symptoms of rat-bite fever. If a rat bites a person, prophylactic antibiotics, such as amoxicillin or amoxicillin-clavulanic acid, may prevent rat-bite fever, but current data do not support the routine use of antibiotics after all rat bites. Some researchers suggest that because of the serious nature of rat-bite fever in young infants, infants younger than 3 months of age who are bitten by a rat should receive antibiotic prophylaxis.⁷⁶

DEFINITION

Bartonella species cause infection in both zoonotic and human hosts and give rise to a wide spectrum of acute or chronic disease symptoms. The development of different manifestations of *Bartonella* disease depends on the immune status of the host. Until 1993, only three human diseases were known to be caused by *Bartonella* species.² However, advances in molecular techniques have led to the reclassification of several pathogens within the family Bartonellaceae, genus *Bartonella*, expanding to include more than 30 validated species.¹¹ Several of these species have been associated with human disease (Table 139.1). The current *Bartonella* genus was created by merging with the genus *Rochalimaea* on the basis of both DNA-DNA hybridization data and comparison of 16s rRNA gene sequences.¹² Of the members of the genus *Rochalimaea* that have been reclassified as *Bartonella* spp., *Bartonella henselae*, the cause of cat-scratch disease (CSD), is the most common *Bartonella*-associated infection in children. *Bartonella* infections other than CSD seldom occur in children and are discussed briefly later in the chapter.

MICROBIOLOGY

Comparisons of the 16s rRNA-encoding genes have shown that the *Bartonella* genus is most closely related to *Brucella* and *Agrobacterium*. *Bartonella* are small, gram-negative, fastidious coccobacilli or slightly curved rods that grow best on enriched blood-containing media in 5% carbon dioxide. Colony morphology varies from small, dry, gray-white colonies to smooth, creamy yellow colonies. Although the optimal growth temperature for *B. bacilliformis* is 28°C, optimal temperatures for other *Bartonella* species range from 35° to 37°C. Even with optimal conditions, these organisms require 1 to 6 weeks to grow in culture.¹³ Increasingly, the presence of *Bartonella* organisms is detected by molecular methods. Organisms of the *Bartonella* genus may colonize human endothelial cells or may persist as intraerythrocytic parasites in the host.²⁴

CAT-SCRATCH DISEASE

CSD, caused by *Bartonella henselae*, is an acute, self-limited infection that begins as a papule or nodule at the site of a scratch or bite by a cat, followed by regional lymphadenopathy. In a small number of patients, more serious systemic complications result, including involvement of the central nervous system, liver, spleen, bone, heart, eyes, or skin. Although CSD was recognized as a clinical entity in the 1930s, the first written report, by Debré from France, was not published until 1950.

Etiology

For more than 40 years, numerous unsuccessful attempts were made to isolate an organism from nodes of patients with CSD. The first clue emerged in 1983, when Wear and colleagues,⁸³ using Warthin-Starry silver stain, demonstrated small, pleomorphic, gram-negative bacilli in lymph nodes and skin papules from patients with CSD. Then, in 1988, an organism was isolated by English and associates²⁵ from the lymph nodes of patients with CSD and was subsequently termed *Afipia felis*. However, the discovery of bacillary angiomatosis and its association with *B. (formerly Rochalimaea) henselae* suggested that it could be the agent responsible for CSD.⁶⁷ In 1992, Regnery and coworkers,⁶⁶ using indirect fluorescent antibody (IFA) assays, demonstrated elevated antibodies to *B. henselae* in serum samples from patients with suspected CSD. We and others,^{2,3} using enzyme-linked immunosorbent assays demonstrated that patients with CSD had significant serologic responses to *B. henselae* and *Bartonella quintana* but not to *A. felis*.^{58,79} These data further supported that the causative agent of CSD was related antigenically to the *Bartonella* genus and not to *Afipia*.⁷⁹ In a physician survey to identify cases of CSD occurring during a 13-month period in cat owners in Connecticut, Zangwill and colleagues⁸⁵ demonstrated that of 45 patients with clinical CSD, 38 had antibody titers of 1:64 or higher to *B. henselae* as compared with only 4 of 112 samples from controls ($P < .001$). Finally, the use of polymerase chain reaction (PCR)

TABLE 139.1 *Bartonella* Species Causing Human Disease

Bartonella Species	Country of First Cultivation	Year of Description	Reservoir Host/Vector	Human Disease
<i>B. alsatica</i>	France	1999	Rabbit	Endocarditis, lymphadenopathy
<i>B. bacilliformis</i>	—	1909	Human/sand fly	Carrión disease, Oroya fever, verruga peruana
<i>B. clarridgeiae</i>	—	1996	Cat/cat flea	Cat-scratch disease
<i>B. elizabethae</i>	United States	1993	Rat	Endocarditis, neuroretinitis
<i>B. grahamii</i>	United Kingdom	1995	Rat, insectivore	Neuroretinitis
<i>B. henselae</i>		1990	Cat/cat flea	Cat-scratch disease, endocarditis, bacillary angiomatosis, bacillary peliosis hepatis, Parinaud oculoglandular syndrome, neuroretinitis, osteomyelitis, arthropathy, bacteremia with fever
<i>B. koehlerae</i>	United States	1999	Cat	Endocarditis
<i>B. mayotimonensis</i>	United States	2009	Unknown	Endocarditis
<i>B. melophagi</i>	United States	2006	Unknown	Bacteremia
<i>B. quintana</i>		1920	Human/body louse	Trench fever, endocarditis, bacillary angiomatosis
<i>B. rochalimae</i>	United States	2007		Bacteremia, fever, splenomegaly
<i>B. tamiae</i>	Thailand	2008		Febrile illness
<i>B. vinsonii</i> subsp. <i>arupensis</i>	United States	1999	Dog, rodent/ticks	Bacteremia with fever, endocarditis
<i>B. vinsonii</i> subsp. <i>berkhoffii</i>	United States	1999	Dog	Endocarditis
<i>B. washoensis</i>	—	2000	Ground squirrel	Myocarditis

Modified from Rolain JM, Rauoult D. *Bartonella* infections. In: Goldman L, Schafer AI, et al, eds. *Cecil Medicine*. 24th ed. Philadelphia: Elsevier; 2012:1907.

confirmed the causative agent of CSD as *B. henselae*.³ Eventually, PCR amplification was used to detect *B. henselae* not only in purulent material aspirated from involved nodes but also in CSD skin test material.^{1,35,74} Subsequently, *B. henselae* has been cultured from lymph nodes obtained from patients with CSD.³²

Transmission

Domesticated house cats are healthy carriers of *B. henselae*, and cat fleas (*Ctenocephalides felis*) play a major role in cat-to-cat transmission. Approximately 90% of patients with CSD have a history of exposure to cats, particularly a scratch or bite from a kitten with fleas. Although cats remain asymptomatic, they serve as a persistent reservoir for *B. henselae*. Reported *B. henselae* seroprevalence rates in cats vary. The southeastern United States, Hawaii, and coastal California have the highest seroprevalence in cats (40–54.7%), whereas rates are much lower (3.7–6.7%) in the Rocky Mountain and Midwestern regions.⁴³ In another study, blood was collected from a convenience sample of 271 pet cats 3 months to 2 years of age in four areas of the United States (southern California, Florida, metropolitan Chicago, and metropolitan Washington, DC). Overall, 65 (24%) cats had *B. henselae* bacteremia, and 138 (51%) cats were seropositive for *B. henselae*. Regional prevalences for bacteremia and seropositivity were highest in Florida (33% and 67%, respectively) and California (28% and 62%, respectively) and lowest in the Washington, DC (12% and 28%, respectively) and Chicago (6% and 12%, respectively) areas.³⁷ In another report, blood samples obtained from domestic and impounded cats in the San Francisco Bay region grew *B. henselae* 27% of the time; kittens were 4.7 times more likely to have a very high bacterial load than were young adult cats.²⁷ Investigators reported that *Bartonella* spp. were isolated from the blood of 4 of 14 (29%) mountain lions and from 7 of 19 (37%) bobcats living in the wild.²⁰ *B. henselae* also was detected in fleas from infected cats by both direct culture and PCR, although no data support flea-to-human transmission.

Interestingly, Chang and colleagues¹⁸ found that *Ixodes pacificus* and *Dermacentor* ticks from five of six California counties were also PCR positive for *B. henselae*. Coinfections with *B. henselae* and *Borrelia burgdorferi* were described in three patients in New Jersey.²⁶ *Ixodes* ticks obtained from two of the three households of patients with CSD were PCR positive for *B. henselae*. More recently, potentially zoonotic strains from six *Bartonella* species were detected in samples from patients who had chronic, subjective symptoms and who reported tick bites. Three strains were *B. henselae*, and three were from other animal-associated *Bartonella* spp. (*B. doshiae*, *B. schoenbuchensis*, and *B. tribocorum*). This investigation identified three novel *Bartonella* spp. strains with human pathogenic potential and showed that *Bartonella* spp. may be the cause of undifferentiated chronic illness in humans who have been bitten by ticks.⁸¹ Thus clinicians should consider *Bartonella* infection in humans after tick bites, although the frequency of transmission is unknown.

Epidemiology

CSD most commonly affects children and young adults worldwide, with regional variations. The Centers for Disease Control and Prevention estimate that, overall, more than 22,000 cases of CSD occur each year in the United States. Using a national inpatient database, Reynolds and coworkers⁷⁰ estimated that 437 pediatric hospitalizations for CSD (0.60 per 100,000 population) occurred in 2000, with 60% between July and October. Rates were higher in children younger than 5 years of age and higher in the southern states, findings underscoring the regional differences. Zangwill and colleagues⁸⁵ suggested that the seasonality of CSD could be explained by the breeding patterns of cats and fleas. Cats often become pregnant in late spring or early fall, and after a 9-week gestation period, kittens are born in early fall or midwinter. Flea breeding peaks during the late summer months.

Pathobiology

Histopathologic examination of the primary inoculation lesion demonstrates dermal necrosis, with variable numbers of histiocytes and occasional multinucleated giant cells accompanied by scattered microabscesses with neutrophils, eosinophils, lymphocytes, and plasma cells. The epidermal changes are nonspecific and consist of parakeratosis, hyperkeratosis, edema, and exocytosis of inflammatory cells. Charac-

teristic findings in the lymph nodes, similar to the primary lesion, include follicular hyperplasia, focal cortical necrosis, and necrotizing granulomas with central microabscesses and palisading histiocytes. A perivascular neutrophilic infiltrate may also be present. Subsequently, the lesions progress to “stellate microabscesses” within small cortical granulomas. Warthin-Starry or Steiner silver impregnation stains may reveal pleomorphic bacilli in clusters or short chains within the areas of central necrosis or around small vessels, particularly in early lesions. Granulomas with microabscess formation also can be found in the liver, spleen, and bone. Because other organisms such as the cause of tularemia, fungi, and mycobacteria may have similar histopathologic characteristics, the histopathologic findings must be correlated with the clinical findings and other laboratory studies, including serology, culture, or PCR.

In vitro studies have identified several additional properties of *B. henselae*. When *B. henselae* infects endothelial cells, it induces activation of nuclear factor- κ B and expression of adhesion molecules, an important step in the pathogenesis of CSD and bacillary angiomatosis.^{18,33} Animal studies have shown that interferon- γ -mediated activation of macrophages is involved in clearing *B. henselae* infection and that microbicidal activity is mediated to a large extent by nitric oxide.⁵⁶ A role for cell-mediated immunity in CSD is suggested by the positive skin test reaction to injected material aspirated from cat-scratch nodes and the granulomatous lesions noted in biopsy specimens.

Clinical Manifestations and Course

The most common clinical manifestation, often referred to as *typical CSD*, is a gradually enlarging regional lymph node occurring 1 to 3 weeks after a scratch or bite from a cat. An inoculation site, which often appears as a red papule 3 to 5 mm in diameter, can be detected in two-thirds of patients. Constitutional symptoms of malaise, fatigue, anorexia, emesis, and headache are common but usually are mild. Fever occurs in less than one-half of the patients with typical CSD, thus rendering the common name “cat-scratch fever” inexact. Physical examination generally reveals a skin papule at the inoculation site and regional lymphadenopathy (Fig. 139.1). In approximately 50% of cases, lymphadenopathy is the only manifestation of the disease and occurs most commonly in the upper extremity (axillary or epitrochlear lymph nodes, 46.1%), the head and neck area (cervical or submandibular, 26.1%), and the lower extremities (femoral or inguinal, 17.5%).¹⁵ Supraclavicular lymphadenopathy, which often raises concern for malignant neoplasm, occurs rarely (2% of typical CSD cases). Suppuration of the involved lymph nodes occurs in approximately 10% of patients (Fig. 139.2). More unusual manifestations of CSD include neuroretinitis, subacute iritis, optic neuritis, focal chorioretinitis, and the oculoglandular syndrome of Parinaud (Fig. 139.3). Patients with this syndrome have painful conjunctivitis without eye drainage and

FIG. 139.2 Purulent material aspirated from an epitrochlear lymph node of a child with cat-scratch disease. The primary lesion was on the index finger.

FIG. 139.3 Child with the oculoglandular syndrome of Parinaud as a manifestation of cat-scratch disease. Note the parotid swelling and the primary site in the right eyebrow. (Courtesy James D. Cherry, MD.)

preauricular adenopathy. Recovery is spontaneous without sequelae within 2 to 4 months after onset.

Hepatosplenic CSD is an important cause of prolonged fever in children and should be included in the differential diagnosis of fever of unknown origin. Often these children have fever for several weeks (mean, 3 weeks), abdominal pain (occurring in about two-thirds of patients),^{5,23} joint pain, headache, weight loss, and chills. Significant lymphadenopathy is lacking in more than 50% of cases, thus rendering the diagnosis problematic. Hepatic or splenic enlargement (or both) is found in one-half of these children, but hepatic transaminase levels usually are normal. Erythrocyte sedimentation rates invariably are elevated and frequently are greater than 100 mm/h. Abdominal imaging usually demonstrates typical granulomatous lesions in the liver or spleen that often are diagnostic of this entity (Fig. 139.4). Although both ultrasonography and computed tomography (CT) demonstrate these lesions, some reports suggest that ultrasound evaluation is more sensitive than CT.^{48,51} As is the case with other infections causing hepatosplenic granulomas, late calcification has been described.

Neurologic complications have been reported in approximately 2% of CSD cases, with an estimated 51 pediatric hospitalizations in 2000.⁷⁰ Encephalopathy, the most common manifestation, typically occurs 1 to 6 weeks after the onset of lymphadenopathy. Fever and seizures

FIG. 139.4 Multiple hypodense lesions in the liver and spleen seen on computed tomography in a child with prolonged fever, abdominal pain, and positive *Bartonella henselae* serologic findings.

develop abruptly, followed by confusion, disorientation, and, occasionally, combativeness. Status epilepticus is well described. Results of cerebrospinal fluid examination frequently are normal, but occasional mild pleocytosis or an elevated protein level is seen. Electroencephalographic findings frequently are abnormal, with diffuse slowing or focal abnormalities. CT findings of the head generally are normal. Resolution of seizures and normalization of mental status often occur as suddenly as does the onset. Neurologic recovery commonly occurs within weeks and almost always is complete within a year. Persistent deficit or a need for prolonged anticonvulsant therapy has been reported in only a few cases.^{38,68} Two immunocompetent children were reported to have central nervous system infection associated with *B. quintana* with a similar symptom constellation.⁵⁹

Osteomyelitis caused by *B. henselae* is well described in publications, with one report documenting its occurrence in 2 of 1200 cases. With improved imaging, serologic methods, and PCR for diagnosis, it is now clear that *B. henselae* osteomyelitis can occur as part of a disseminated infection, in the setting of otherwise typical CSD, or as a seemingly isolated manifestation.^{41,82} The pathogenesis is not clear, but it probably represents hematogenous spread, although local spread from a lymph node or abscess has been reported. Although the presentation of osteomyelitis may be acute, many patients have weeks to months of pain and intermittent fever before the diagnosis is made. A high proportion of reported cases involves the axial skeleton, most commonly the vertebral column. In a review of 47 cases by Hajjaji and colleagues,³⁹ lesions in the vertebrae or pelvic girdle were present in more than 50% of cases. Involvement of the long bones of the limbs, the sternum, and the skull has also been described. Although single-site involvement is typical, multifocal involvement was present in 28% of the cases in the review by Hajjaji and colleagues.³⁹ Most commonly, the bony lesions identified by plain film, CT, or magnetic resonance imaging are osteolytic. Magnetic resonance imaging also may show periosteal reactions, marginal sclerosis, and bone marrow lesions without cortical destruction, which are seen as hyperintense foci on T2-weighted images.

Patients with CSD also may have skin lesions other than at the inoculation site, including maculopapular rash, erythema nodosum, and petechiae secondary to thrombocytopenia. Molecular techniques have also documented hepatitis, hemolytic anemia, atypical pneumonia, pulmonary nodules, an infectious mononucleosis-like syndrome, and disseminated bartonellosis. Bacillary angiomatosis (mixed neovascular and inflammatory lesions in the skin or viscera), bacillary peliosis (dilated capillaries or multiple blood-filled cavernous spaces in the liver, spleen, or lymph nodes), and relapsing fever with bacteremia caused by *B. henselae* also can develop in immunocompromised subjects.⁵³

Hemophagocytic lymphohistiocytosis, an uncommon multisystem disorder that may be triggered by infection, was also reported following

B. henselae infection, in an 11-year-old immunocompromised renal transplant recipient. Early recognition of hemophagocytic lymphohistiocytosis allowed for more directed therapy with eventual resolution.⁶² CSD has also been reported in patients undergoing immunomodulatory therapy for rheumatologic diseases.^{75,88}

ENDOCARDITIS

Epidemiology

Bartonella spp. have been reported as the cause of endocarditis in more than 100 cases,⁶⁴ with most cases in adults and several in adolescents. Often the culture results are negative.^{7,61,63,77} In a series from a large referral laboratory in France, *Bartonella* species accounted for 28% of cases of culture-negative endocarditis, whereas in another report *Bartonella* accounted for only 3% of culture-negative cases. *B. quintana* predominates and accounts for roughly 75% of cases of endocarditis. *B. henselae* causes most of the remaining cases, and other species (*Bartonella elizabethae* and *Bartonella vinsonii*) have been reported in isolated cases. The epidemiologic characteristics of the patients differ considerably between the main two causative species. *B. quintana* endocarditis is highly associated with homelessness, chronic alcoholism, and body lice and is less likely to occur in the setting of cat exposure and underlying valvular heart disease. Endocarditis cases resulting from *B. quintana* infection also have been described in persons immunocompromised by infection with human immunodeficiency virus (HIV).^{63,76} In contrast, *B. henselae* endocarditis occurs most often in patients with underlying valvulopathy (90%) and clearly is linked to exposure to cats or fleas.³⁰

Clinical Manifestations

Bartonella endocarditis has a subacute presentation with fever, heart murmur, and often evidence of heart failure. Prolonged fever, night sweats, and profound weight loss also may occur. The aortic valve usually is affected; right ventricular or prosthetic valve involvement is an unusual finding. Valvular surgical intervention is needed in many cases, often because of a delay in diagnosis.

BARTONELLOSIS (CARRIÓN DISEASE)

Bartonellosis is a term that has been used to describe a distinct disease seen in Peru, Ecuador, and Colombia and that is caused by *Bartonella bacilliformis*. *B. bacilliformis* causes two distinct illnesses: Oroya fever, a severe type of febrile hemolytic anemia; and verruga peruana, an eruption of hemangioma-like lesions.

The first written account of bartonellosis is attributed to Gago de Vadillo, who published a treatise on the subject in 1630. Then, in 1764, Cosme Bueno first described the vector of this disease and of cutaneous leishmaniasis as the uta or sand fly.⁴⁰ In the mid-1800s an epidemic occurred that took the lives of hundreds.⁷³

In 1885, a Peruvian medical student (Carrión) was collecting data on the geographic distribution and clinical features of verruga peruana. To study disease symptoms in the pre-eruption period of verruga, he inoculated himself with material taken from a patient with verruga. Within 21 days after inoculation he became symptomatic, developed classic Oroya fever, and died. In 1905, Alberto Barton, a Peruvian physician, described the etiologic agent (*Bartonella bacilliformis*), but several years passed before this organism was accepted as the cause of Oroya fever and named in his honor.

Epidemiology

Historically, the distribution of bartonellosis has been restricted to the mountain valleys of the Andes Mountains in Peru, Ecuador, and Colombia between the altitudes of 500 and 3200 m above sea level and primarily in valleys that are at right angles to the prevailing wind. The distribution of disease reflects the presence of the sand fly vector *Lutzomyia verucurum*, which is seen only at these altitudes. The disease is usually acquired at twilight or soon thereafter because of the feeding habits of the insects. Within the region, the disease is endemic, but with sporadic epidemic outbreaks.^{36,46}

Pathobiology

After inoculation by the sand fly, *Bartonella* organisms enter the endothelial cells of the blood vessels, where they proliferate. Microscopically, masses of organisms are noted within the cytoplasm of the cells lining the blood vessels and lymph channels, thus causing the lumen of the vessel to bulge. The organisms may also be found in reticuloendothelial cells in the lymph nodes, liver, and spleen, as well as within the bone marrow, kidneys, adrenals, pancreas, and rarely, the skin, heart, and lungs of infected patients.⁹ They also parasitize erythrocytes and cause indentations and deformation of the erythrocyte membrane, membrane fusion, and entrance of the organisms into intracellular vacuoles, where they replicate.¹⁰ Severe anemia results from destruction of the parasitized cells, with as many as 90% of the erythrocytes involved. However, all parasitized cells are not destroyed, and no hemolysins or agglutinins have been recovered.⁶⁹ Cuadra and Takano²² showed that the parasites are located predominantly within cells, rather than on the surface. In the recovery phase, the rod-shaped organisms change to a more coccoid form and rapidly disappear from the blood.

A patient who survives the acute phase of Oroya fever may or may not experience cutaneous manifestations of the disease, which appear as nodular, hemangiomatous lesions ranging from a few millimeters to several centimeters. Light microscopy reveals angioblastic and histiocytic hyperplasia of the dermis. Numerous newly formed small vessels with endothelial cell proliferation are found. Mast cells, lymphocytes, and macrophages are present.⁴ Electron microscopy demonstrates that the bacterial organisms are located within the verruga, extracellular in the fine fibrous interstitium.⁶⁵ In vitro studies have shown that *B. bacilliformis* stimulates endothelial cells, and in vivo studies have shown angiogenic activity. This finding may explain the similar pathologic findings of verruca and bacillary angiomatosis produced by other *Bartonella* spp.⁴ One article summarized the current state of knowledge on *B. bacilliformis* and reviewed its host-cell parasitism, molecular pathogenesis, phylogeny, sand fly vectors, diagnostics, and prospects for control.⁵⁵

Clinical Manifestations

The incubation period of bartonellosis varies from 2 to 14 weeks, with a mean of 3 weeks. Some patients are totally asymptomatic, and disease is detected only by blood culture or on serologic survey. In a population-based cohort study, 0.5% of participants had asymptomatic bacteremia.¹⁷ Other patients develop only headache, malaise, and occasional fever, with *B. bacilliformis* recovered from blood cultures. Still others have severe anemia (Oroya fever), are febrile, and are deeply apathetic, with a peculiar discoloration of their skin and sclerae.⁷¹ Tachycardia and soft murmurs are noted; occasionally, peripheral vascular collapse occurs. Clouding of the sensorium and delirium are common findings; these effects usually are mild but may progress to overt psychosis. The body temperature usually fluctuates between 37.5°C and 38.5°C (99.5°F and 101.3°F). Physical examination discloses generalized lymphadenopathy and nonpainful hepatomegaly.⁵⁰

Laboratory studies reveal anemia that is macrocytic and hypochromic, with anisocytosis and poikilocytosis. The erythrocyte count may drop to as low as 500,000/mm³ in the first 2 to 4 weeks of illness, with reticulocytes increasing to 50%. The pathognomonic sign of the disease is the presence of *B. bacilliformis* within Giemsa-stained erythrocytes as red-violet rods. The leukocyte count may be normal, low, or elevated.

The “critical stage” of the anemia is the period of transition when the organism suddenly disappears from the erythrocytes. In as many as 40% of patients, the illness becomes more severe, with the development of an intercurrent infection, particularly with *Salmonella*.²¹ In the pre-eruptive stage, patients may complain of pain in their joints, bones, and muscles, as well as cramps and paresthesias, but the anemia and lymphadenopathy of the invasive stage disappear.

The appearance of red cutaneous nodules, or verruga, is pathognomonic of the disease in the eruptive stage. Usually, these nodules are present in the skin, but they may also be found in mesenchymatous tissue. They vary greatly in number and size, from small, asymptomatic nodules to disfiguring zonular (hemangioma-like) lesions. This stage

may last from several months to a year and may be the sole manifestation of the disease, particularly in school-aged children in endemic areas.

TRENCH FEVER

Epidemiology

Trench fever (from *B. quintana*) was first described in Russia during World War I, when more than 1 million troops were infected.⁹ The human body louse, *Pediculus humanus* var. *corporis*, is the vector, with humans the only known reservoir.

Clinical Manifestations

After an incubation period that is extremely variable (from 4 to 35 days, with an average of 22 days), one of four major fever patterns results: (1) a single febrile episode; (2) a single febrile period lasting 4 to 5 days; (3) three to eight recurrent febrile episodes, each lasting 4 to 5 days (sometimes for a year or more); or (4) persistent fever lasting 2 to 6 weeks.^{29,78} Associated signs and symptoms include conjunctival injection, retroorbital pain, myalgias, arthralgias, headache, bone pain (especially in the shins), and splenomegaly. Chronic bacteremia following clinical improvement is common.²⁹

BACILLARY ANGIOMATOSIS AND BACILLARY PELIOSIS HEPATIS

Etiology

Both *B. henselae* and *B. quintana* can cause vasculoproliferative disorders, which typically occur in immunocompromised persons, primarily adults with acquired immunodeficiency syndrome (AIDS) and with very low CD4⁺ counts, and, to a lesser extent, in adults with cancer or recipients of organ transplants. Although these infections are exceptionally rare in children, reports have described bacillary angiomatosis in a child infected with HIV,¹⁹ a child undergoing chemotherapy,⁵⁷ and, more rarely still, children who are thought to be immunocompetent.⁸⁶ Vasculoproliferation can also manifest as cutaneous or subcutaneous lesions (bacillary angiomatosis, caused by *B. henselae* or *B. quintana*) and pathologically can resemble the verruga of *B. bacilliformis* infection or solid organ lesions (bacillary peliosis hepatitis, caused only by *B. henselae*).

Clinical Manifestations

Characteristically, the vasoproliferative lesions of bacillary angiomatosis are red with a collarette of scale, but the clinical findings can be diverse. Deep soft tissue masses may develop, and trauma may result in ulceration or bleeding. Osseous lesions occur in the long bones and can be very painful. The central nervous system, bone marrow, and mucosal surfaces of the gastrointestinal and respiratory tracts may also be involved.

Bacillary peliosis hepatitis is seen primarily in HIV-infected adults who have fever and abdominal pain. In these patients, vascular proliferative lesions develop, primarily in the liver and spleen, although the abdominal lymph nodes and bone marrow may also be involved. This disease has not been reported in children.

DIAGNOSIS

Cat-Scratch Disease

Until recently, the clinical diagnosis of CSD required the presence of at least three of the following: a history of contact with a cat and the presence of a scratch or a primary lesion; a positive skin test result using material obtained from a purulent node from a patient with CSD; regional lymphadenopathy with negative studies for other potential causes of lymphadenopathy; and characteristic histopathologic findings on a biopsy specimen. The difficulty in isolating organisms from routine cultures of lymph nodes or other tissue specimens from patients with suspected CSD required the use of this strict clinical definition. In addition, an intradermal skin test composed of heated purulent lymph node material from patients with CSD was used for many years as a skin test reagent. Although the skin test was 90% to 98% sensitive and specific for the diagnosis of CSD, the material was not readily available,

was not standardized, and was not licensed for routine use. In addition, the potential for transmission of other infectious agents with this test currently prohibits its use.

Specific diagnostic tests to assess serum antibodies against *B. henselae* such as IFA, enzyme-linked immunosorbent assay, and PCR amplification to identify *B. henselae* DNA sequences in tissues have reduced the need for the skin test and for invasive diagnostic procedures. Giladi and colleagues³⁴ developed a new enzyme immunoassay (EIA) for immunoglobulin (Ig) M and IgG that uses *N*-lauroylsarcosine-insoluble outer membrane antigens from agar-grown *B. henselae* and demonstrated increased sensitivity. This study determined the EIA sensitivity to be 75% for anti-*B. henselae* IgG alone, 48% for IgM alone, and 85% overall when positive IgG, IgM, or both were accepted as diagnostic. Another study³⁴ evaluated the kinetics of anti-*B. henselae* IgM and IgG antibodies by using EIA. Forty-eight (92%) of the 52 IgM-positive patients became IgM negative within 3 months after the onset of disease; 208 (93%) of 223 serum samples tested positive for anti-*B. henselae* IgG. Beyond 6, 12, and 24 months, 35%, 25%, and 25% of serum samples (and patients), respectively, remained IgG positive. Some investigators have suggested that a single IgG titer greater than 1:256 is reliably diagnostic of acute infection. For any manifestation of CSD, detection of a significant rise in titer between acute and convalescent sera is confirmatory. However, cross-reactions between antibodies directed toward *B. henselae*, *B. quintana*, and *Chlamydia* spp. can render interpretation problematic. Cross-adsorption and Western immunoblotting can overcome this problem.⁴²

Histopathologic examination of cat-scratch tissue includes granuloma formation with microabscesses and follicular hyperplasia. A Warthin-Starry stain and culture (ideally plated on both chocolate and rabbit blood agar and co-cultivated with eukaryotic cells) may be performed, although neither has high sensitivity. Very strain-specific assays involving PCR amplification of the 16S rRNA gene, the citrate synthase gene (*gltA*), or the *htrA* gene of *B. henselae* offer improved sensitivity over culture and can be useful in establishing a diagnosis when purulent lymph node aspirates or other infected tissues are obtained.²⁸

One report described a new detection method that combines enrichment culture and molecular amplification, which increases the testing sensitivity. This method detected DNA from at least 1 *Bartonella* species in 32 (28%) of the 114 veterinary subjects.⁴⁷ After DNA sequencing, the *Bartonella* species were determined for 27 of the 32 infected subjects, including *B. henselae* in 15 (56%), *B. vinsonii* subsp. *berkhoffii* in 7 (26%), *B. koehlerae* in 6 (22%), and a *B. volans*-like sequence in 1 (4%). This study suggests that cryptic *Bartonella* bloodstream infection may be more frequent in humans than previously recognized.

The differential diagnosis of CSD includes other forms of bacterial adenitis, typical or atypical mycobacterial infections, lymphogranuloma venereum, infectious mononucleosis, tularemia, plague, sporotrichosis, blastomycosis, histoplasmosis, syphilis, HIV infection, neoplasm, and sarcoidosis.

Endocarditis

The diagnosis of endocarditis is generally made with the use of serologic or PCR techniques; however, among patients with culture-negative endocarditis, a single IgG titer of 1:800 or higher has a 95.5% positive predictive value for *Bartonella* as the cause.³¹ Because results of PCR of blood rarely are positive, PCR of valvular tissue is the most sensitive method to diagnose endocarditis. Special culturing techniques, including the use of Isolator tubes, and prolonged incubation may be helpful, in addition to serologic tests, histopathologic examination of valvular tissue, and PCR.⁸⁷

Bartonellosis

The diagnosis of bartonellosis is made on the basis of clinical manifestations, Giemsa-stained blood smears showing typical organisms, or positive blood culture results. The presence of typical verruga in patients from an endemic area is pathognomonic of the disease. IgM antibody may be present in both stages of the disease, as well as in some asymptomatic persons.^{36,44} Persons with typical Oroya fever who are treated with antibiotics may not have an antibody response.^{36,44} An IFA assay

has shown promise for evaluating patients in both the acute and convalescent phases of the disease.¹⁶ The differential diagnosis in the initial phase includes typhoid fever, malaria, tuberculosis, leptospirosis, brucellosis, and meningitis, as well as hematologic malignant disease and aplastic or hemolytic anemia. The eruptive phase may resemble hemangiomas, bacillary angiomatosis, Kaposi sarcoma, and other nodular diseases.

Trench Fever

In a nonepidemic situation, establishing the diagnosis of trench fever is very difficult because the manifestations are not distinctive. The relapsing form can mimic malaria or *Borrelia recurrentis* relapsing fever. A history of body louse infestation or association with an epidemic should heighten suspicion. *B. quintana* can be cultured from blood by using a modification that includes culturing on epithelial cells. Serologic testing is available; however, cross-reactions with *B. henselae* occur.

Bacillary Angiomatosis and Bacillary Peliosis Hepatis

Given the difficulty with culture and the poor reliability of serologic studies, the diagnosis of these diseases relies on direct visualization of the organisms in tissue samples on electron microscopy or with Warthin-Starry stain or, increasingly, on detection of the organism in the affected tissue by PCR. The differential diagnosis of bacillary angiomatosis includes Kaposi sarcoma, pyogenic granuloma, verruga peruana, and multiple other opportunistic infections. The differential diagnosis of bacillary peliosis hepatis includes hepatic Kaposi sarcoma, lymphoma, extrapulmonary pneumocystosis, and infection with *Mycobacterium avium-intracellulare*.

TREATMENT

Cat-Scratch Disease

In an immunocompetent host, typical CSD is self-limited and resolves spontaneously in 1 to 2 months without the use of antibiotics. Application of moist soaks and local heat, use of analgesics, limitation of activity of the affected limb, and aspiration of fluctuant material in the nodes (in some instances, done serially) may relieve the pain and resolve the inflammation. Excisional biopsy of chronically involved lymph nodes also can be performed occasionally to rule out other treatable causes. However, conflicting data exist in publications regarding whether antibiotic therapy is ever helpful in normal hosts. Macrolides, fluoroquinolones, trimethoprim-sulfamethoxazole (TMP-SMX), doxycycline, and β -lactam agents all have in vitro activity against the organism, but gentamicin and rifampin appear to be the only bactericidal agents. Because in vitro susceptibility testing is technically challenging, lacks standards for interpretation of results, and produces minimum inhibitory concentrations that have correlated poorly with clinical efficacy, it often is not useful.⁷² In Margileth's⁵² retrospective review of 202 patients treated with antibiotics for CSD, rifampin was more effective than ciprofloxacin, gentamicin, or TMP-SMX. Another prospective, randomized, double-blind, placebo-controlled study using oral azithromycin for 5 days was effective in reducing lymph node volume measured by three-dimensional ultrasonography.⁸ Adults and children weighing more than 100 lb were given an initial single dose of 500 mg azithromycin on day 1 of treatment and 250 mg on days 2 to 5 as single daily doses. Patients weighing less received the liquid preparation of 10 mg/kg on day 1 and 5 mg/kg on days 2 to 5.

No randomized, prospective, controlled studies have evaluated therapy for the systemic manifestations of CSD. In one retrospective review, children with hepatosplenic CSD who were given rifampin, 20 mg/kg per day in two doses for 14 days, either alone or in combination with another agent, experienced a decreased duration of fever.⁵ In the same retrospective review, gentamicin or TMP-SMX also led to defervescence within 5 days, but penicillins, cephalosporins, tetracycline, and erythromycin had minimal or no clinical efficacy. In 2004, evidence-based treatment recommendations for *Bartonella* infections were published, and no recommendations for typical CSD, hepatosplenic CSD, or osteomyelitis were presented.⁷² Outcomes of hepatosplenic disease and osteomyelitis caused by *B. henselae* generally have been excellent with

or without antibiotic therapy or surgical intervention. Suggested therapy for central nervous system disease includes doxycycline and rifampin; however, no data suggest that antibiotic treatment of CSD encephalopathy is beneficial. Reports of the duration of antibiotic therapy have varied from 5 days in immunocompetent patients to 6 weeks in patients with atypical CSD or in immunocompromised patients.

Corticosteroid therapy has been reported in a small number of cases, including patients with typical CSD, retinal involvement, hepatosplenic disease, or encephalopathy, as well as in a single immunocompromised patient with fever and diffuse lymphadenopathy.^{14,15,49,84} Because the pathogenesis of CSD with prolonged symptoms may include a postinfectious, inflammatory process,^{14,72} corticosteroids appear to have some theoretical role. Despite the reported anecdotal successes, however, corticosteroids are not recommended for routine treatment of any manifestation of CSD.

Endocarditis

Initial empiric treatment of culture-negative endocarditis with ceftriaxone and gentamicin is effective for *Bartonella* organisms. A retrospective analysis of 101 adult patients with endocarditis showed a benefit with the use of an aminoglycoside as part of a treatment regimen for a minimum of 14 days. If a *Bartonella* infection is proven, doxycycline in combination with gentamicin is recommended. The recommended duration of ceftriaxone or doxycycline therapy is 6 weeks, with gentamicin combination therapy for the first 14 days.⁶

Bartonellosis

B. bacilliformis is sensitive to many antibiotics, including penicillin, tetracycline, streptomycin, and chloramphenicol. With treatment, the fever usually abates by 24 hours; the rod-shaped organisms change to more coccoid forms and soon disappear from the blood. The choice of antibiotic may be guided by considerations other than simple eradication of *B. bacilliformis*, including the risk for developing intercurrent infection. Chloramphenicol is considered to be the drug of choice because it also is useful in the treatment of salmonellosis.⁸⁰ Occasionally patients need the addition of another antibiotic, usually a β -lactam agent.⁷² Blood transfusions may be helpful during the period of severe anemia, especially if blood is obtained from patients who have recently recovered from the disease.⁶⁹

Treatment of verruga peruana usually is not necessary unless particularly large zonular lesions interfere with function; in these persons, surgical treatment may be necessary. Treatment is considered when there are more than 10 cutaneous lesions, when lesions are particularly erythematous or violaceous, or when the onset of lesions was more than 1 month before presentation. Oral rifampin, ciprofloxacin, or tetracycline with or without gentamicin may be used to aid in healing of the cutaneous lesions.^{11,51,72}

Trench Fever

No controlled trials of treatment of trench fever have been performed, but dramatic defervescence has been noted with the use of tetracycline and chloramphenicol.^{45,78} Recommended therapy for *B. quintana* bacteremia is doxycycline in combination with gentamicin.¹¹

Bacillary Angiomatosis and Bacillary Peliosis Hepatis

Both bacillary angiomatosis and bacillary peliosis hepatis have been treated successfully with antimicrobial therapy, including erythromycin, azithromycin, or clarithromycin for 3 months for bacillary angiomatosis or for 4 months for bacillary peliosis hepatis.^{45,60,78} The duration of therapy is critical to prevent relapses. Doxycycline may be used as an alternative regimen.

PROGNOSIS AND PREVENTION

Arthropod control should be recommended for prevention of transmission of *Bartonella* species to humans, particularly with regard to pet ownership for immunocompromised patients. Routine veterinary visits and control of flea and tick infestations in young kittens are the current practical preventive measures for CSD. Currently, no vaccine is available to prevent *Bartonella* infections in animals or humans.

Typically, the prognosis of CSD is excellent without any sequelae. Although patients with atypical findings and involvement of other organs may have a prolonged course and antibiotics may be used, the prognosis is good. Reinfection occurs only rarely. Although the mortality rate in patients with *Bartonella* endocarditis has been reported to be as high as 30%, more recent series have shown lower rates (7%). The mortality rate in untreated bartonellosis in the past was estimated at approximately 40%. However, the fatality rate was reported as approximately 9% in hospitalized patients and 0.7% in a population-based study.^{44,46} Intercurrent *Salmonella* infection increases the mortality rate. Treatment with chloramphenicol improves prognosis, and permanent immunity develops in most patients. Treatment of trench fever with antimicrobial therapy improves outcomes and prevents progression to more severe disease, such as endocarditis. Antibiotics are usually effective for bacillary angiomatosis and bacillary peliosis hepatitis, although prolonged courses are needed.

SUBSECTION VI Treponemataceae

140

Lyme Disease

Sunil K. Sood • Peter J. Krause

Lyme borreliosis or Lyme disease is caused by a group of spirochetal bacteria (genus *Borrelia*) that are transmitted by several hard-bodied ticks of the genus *Ixodes*. It is found in the temperate zones of North America and Eurasia and is the most common tick-borne disease in these regions. The name Lyme disease dates from the late 1970s, but the first description of the disease was published in 1883, when a German physician described the chronic skin manifestation later named acrodermatitis chronica atrophicans (ACA).^{14,92} The hallmark expanding erythema chronicum migrans (ECM) rash of acute Lyme disease was first reported by a Swedish physician in 1909.² About half a century later, a Wisconsin physician provided the first description of the disease in the New World and reported successful treatment with penicillin.⁷⁸ A small cluster of cases of ECM observed in 1975 in Connecticut and Massachusetts occurred in the same year the Connecticut Health Department and Yale University rheumatologists responded to reports from the public of several children with arthritis in and around the towns of Lyme, Old Lyme, and East Haddam in southeastern Connecticut.^{39,56} Ultimately 51 cases of arthritis (39 children and 12 adults) associated with ECM rash were documented and given the name *Lyme arthritis*.⁹⁸ Lyme arthritis was subsequently recognized to be part of a multisystem disease that was named *Lyme disease*.

ORGANISMS

The microbial etiology of Lyme disease was established in 1983 when Willy Burgdorfer discovered spirochetes in *Ixodes* ticks from Shelter Island, New York¹⁵ and when the same organism was isolated from cultures of blood, skin lesions, and cerebrospinal fluid (CSF) of patients from Connecticut and Long Island, New York.^{11,97} The pathogen was named *Borrelia burgdorferi* and was soon linked to the ECM rash in

European patients, which is now called *erythema migrans*.⁴⁴ The name *Borrelia burgdorferi* sensu lato (“sensu lato” meaning “in a broad sense”) indicates that other genospecies are included under this group name (Table 140.1). At least three other genospecies (*B. afzelii*, *B. garinii*, and *B. bavariensis*) are established causes of Lyme disease in Eurasia and account for variation in the clinical presentation on that continent. *B. afzelii* is strongly associated with ACA and is a common cause of erythema migrans; *B. garinii* is associated with neurologic infection. In addition, there are a few reports of *B. bissettii*, *B. lusitaniae*, *B. spielmanii*, and *B. valaisiana* isolates from Lyme disease patients.⁷⁷ In North America, Lyme disease is caused by the genospecies *B. burgdorferi* sensu stricto (“meaning in a narrow sense”). *B. burgdorferi* is a slow-growing bacterium with a cell membrane that is covered by a loosely associated outer membrane and by flagella that account for the coiled shape of the microorganism and provide motility. In 2016, a new genospecies of *Borrelia* was found to cause Lyme disease in the United States and was named *B. mayonii* after the site of its discovery at the Mayo Clinic. The likely vector is *Ixodes scapularis*, the same as for *B. burgdorferi*.⁶⁸

EPIDEMIOLOGY

Lyme disease is the most commonly reported vector borne illness in the United States and was the sixth most common Nationally Notifiable Disease in 2015. In that year, 28,453 confirmed and 9616 probable cases were reported to the Centers for Disease Control and Prevention (CDC; incidence 8.9 cases per 100,000 population), but the actual number of infections is estimated at 10- to 12-fold higher.^{18,47,57,58,95} Lyme disease—endemic areas in the United States are primarily located in the Northeast and northern Midwest. (Fig. 140.1). Almost all (95%) of the confirmed cases in 2015 were reported from 14 states in these regions

FIG. 140.1 Reported cases of Lyme disease—United States, 2015. One dot represents one case of Lyme disease and is placed randomly in the patient's county of residence. The presence of a dot in a state does not necessarily mean that Lyme disease was acquired in that state. The place of residence is sometimes different from the location where the patient became infected. (From Centers for Disease Control and Prevention. National Center for Emerging and Zoonotic Infectious Diseases, Division of Vector-Borne Diseases.)

(Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont, Virginia, and Wisconsin).¹⁸ Far fewer cases are reported from the northern Pacific Coast region.³¹

In Europe the incidence varies among countries, in part because of different reporting methods and because of travel. The highest incidence is generally in the temperate zone between latitudes 42 and 62 degrees North.⁹² Lyme disease is more common among children than adults, presumably because of their increased exposure to *Ixodes* ticks, with about one-fourth of all reported cases occurring in children younger than 14 years.^{9,90}

Lyme disease is a zoonotic infection that involves multiple hosts and reservoirs.⁵⁴ *Ixodes* ticks take a blood meal from a vertebrate host in each of the three active stages during their 2-year life cycle (larva, nymph, and adult). Spirochetes are ingested during a blood meal from an asymptomatic infected reservoir host and transmitted to other reservoir hosts or to humans by the nymphal or adult stages during a subsequent blood meal. The primary reservoir hosts are the white-footed mouse (*Peromyscus leucopus*) in the Northeast and Midwest and the western gray squirrel and western fence lizard in the Pacific Coast region. Other small mammals such as chipmunks and some species of birds may also serve as reservoir hosts.⁶⁶ White-tailed deer (*Odocoileus*

virginianus) provide an important habitat for adult ticks during the winter season. They do not become infected with *B. burgdorferi* but amplify the tick population by providing an area for procreation and a blood meal for adult ticks. An increase in the deer population over the past few decades is an important factor in the increase in the *I. scapularis* population and in the number of Lyme disease cases in the United States.⁷⁰ Domestic animals such as the dog may carry adult *Ixodes* ticks but do not appear to be important reservoir hosts for the tick, even though dogs can be infected with *B. burgdorferi*. The tick vectors in Europe have a greater variety of reservoir hosts, including ground-feeding birds such as blackbirds, small mammals such as *Apodemus* mice, and medium-sized mammals such as hedgehogs.⁹²

PATHOGENESIS

Borrelia spirochetes are deposited in the skin during tick feeding. The organism does not produce toxins, so disease is primarily a result of the immunologic host response. Major antigens of the bacteria include the outer-surface lipoproteins (Osp) A, B and C, as well as the flagellar protein. Outer surface proteins are important for survival both in the tick and in mammalian hosts.^{69,103} Innate immune activation begins with spirochete binding to pattern recognition receptors such as toll-like receptors on dendritic cells and macrophages in the dermis.^{13,40,53,74} This initiates signal transduction pathways that result in production of chemokines and cytokines by macrophages and dendritic cells.^{53,75} Spirochetes are ingested by macrophages and neutrophils and degraded within phagocytic vacuoles.⁷⁵ Degradation products bind to intercellular pattern recognition receptors that further amplify the inflammatory response.⁷⁵ Adaptive immune responses also help to clear spirochetes. *Borrelia*-specific T cells are activated. These aid in macrophage killing and help B cells differentiate into antibody-producing plasma cells.⁶⁹ Patients with Lyme arthritis typically have higher *Borrelia*-specific antibody titers than do patients with other manifestations of Lyme disease.²⁴ Despite a vigorous immune response, the spirochetes are not immediately killed, partly owing to immune evasion strategies, such as downregulation of expression of outer surface proteins and antigenic variation from the variable major protein-like sequence expression locus (VlsE).^{26,69} *B. burgdorferi* produces specific proteins that inhibit complement activity.⁵¹

Surviving *Borrelia* can disseminate from the skin to other tissues through blood and possibly also through tissue planes. During dissemination within humans, *B. burgdorferi* attach to certain host integrins. This elicits a proinflammatory response that includes production of both matrix glycosaminoglycans and extracellular matrix proteins, which may explain the organism's tropism for particular tissues (e.g., collagen fibrils in the extracellular matrix of the heart, nervous system, and joints).⁶⁹ Dissemination appears to be genotype or strain dependent, with some strains more likely to disseminate than others.^{107,108} Furthermore, infection with specific *B. burgdorferi* genotypes may result in unique clinical manifestations of disease. For example, only the European species *B. afzelii* causes chronic skin lesions of ACA. Long-term immunity is incomplete because episodes of Lyme disease may reoccur in some people. Reinfection has been found in about 3% of children and 10% of adults.^{33,58,111,112}

Several lines of evidence suggest that persistent symptoms do not result from active infection. Synovial tissue from patients with Lyme arthritis typically shows hypertrophy, vascular proliferation, and a marked mononuclear cell infiltrate, but joint cultures in patients with recurrent arthritis are negative.^{13,96} Some adult patients with Lyme arthritis, particularly those with HLA-DRB1 alleles, will develop a chronic, antibiotic refractory, autoimmune arthritis.⁹⁶ Antibiotic refractory Lyme arthritis may be due to *B. burgdorferi* breakdown components that can persist near cartilaginous tissue and induce an inflammatory response after treatment is completed.¹³ Meningitis results from direct invasion of the subarachnoid space by *B. burgdorferi*, as shown by the presence of spirochetes in cultures of CSF. *B. burgdorferi* infiltrates the connective tissue sheath surrounding each bundle of peripheral nerve fibers in the peripheral nervous system in a monkey model.⁷³ There is no evidence to suggest that long-term neurologic symptoms are due to persistent *Borrelia* infection, however.

CLINICAL MANIFESTATIONS

The clinical presentation of Lyme disease in children includes a few well-characterized manifestations that are classified as early or late. Early manifestations are defined as those that begin within 8 weeks after the tick bite and are further characterized as early localized or early disseminated disease.^{81,105} In North America, about 90% of children have erythema migrans, either as a single lesion or as multiple erythema migrans. The remainder present with arthritis, facial palsy, aseptic meningitis, or carditis.³³ Some children with early Lyme disease present with more than one manifestation. In Europe, neurologic manifestations are significantly more common in children (17–38% of cases) than in adults, and Bannwarth polyradiculoneuritis is more common.^{19,90} Borrelial lymphocytoma only occurs in Europe and is common in children.^{59,67}

Early Localized Disease

Erythema Migrans

The initial disease manifestation of Lyme disease is a single erythema migrans lesion that begins at the site of the tick bite and appears after an incubation of about 1 to 31 days (mean of 10 days) (Fig. 140.2A–C). This generally consists of a flat red rash that expands over days. The bull's-eye shape with central clearing is firmly entrenched in both the lay and medical literature but occurs in only two-thirds of skin biopsy or culture-proven erythema migrans.⁶¹ Although the lesion is usually painless, there may be mild stinging, warmth, pruritus, hyperesthesia, or dysesthesia. Vesicular, urticarial, scaling, purpuric, and noncircular variants are well documented.^{61,86} There can be alternating rings of lighter and darker erythema or triangular lesions in areas like the inguinal region. Patients with erythema migrans often have mild constitutional

symptoms including low-grade fever. Because small ring-shaped lesions from insect bites are common in children, practitioners should not rush to diagnose erythema migrans in a child with a focal rash of that type. Close follow-up will establish the diagnosis if the lesion attains a diameter of at least 5 cm, the minimum diameter required to meet the CDC 2017 surveillance case definition of erythema migrans. Rashes that suggest erythema migrans have been observed in nonendemic southern states and recently in a child on Long Island, New York, following bites of Lone Star ticks.^{16,29} This entity has been given the name *southern tick-associated rash illness* (STARI), and although not due to *B. burgdorferi* infection, the causative organism is unknown.

Early Disseminated Disease

Spirochetemia can occur shortly after the tick bite, leading to disseminated skin, neurologic, cardiac, and musculoskeletal manifestations.

Multiple Erythema Migrans

Multiple erythema migrans are the most common form of early disseminated Lyme disease (Fig. 140.2D).^{6,87} Lesions can be distinguished from erythema multiforme by the fact that all are morphologically similar, although they vary in size. A single secondary lesion may occur at the site of a primary lesion that has disappeared. The child also may report constitutional symptoms.

Neurologic Manifestations

Acute neurologic Lyme disease is another common form of early disseminated infection, almost always presenting as seventh cranial nerve palsy, lymphocytic meningitis, or both.^{10,88} Because these manifestations may be due to other etiologies and Lyme disease can be treated with

FIG. 140.2 (A) Erythema migrans scalp lesion only partially visible on the face. (B) Erythema migrans oval lesion. (C) Erythema migrans dark annular lesion. (D) Multiple erythema migrans. (E) Borrelial lymphocytoma. Five-year-old girl from southern California who, while visiting Norway in August 2006, had a tick removed from her left ear lobe. (From Sood SK, editor. *Lyme Borreliosis in Europe and North America*. Hoboken, NJ: John Wiley & Sons; 2011. A–C, Courtesy Vijay Sikand, MD; D, courtesy Lorry Rubin, MD; E, courtesy Mark Salzman, MD.)

antibiotics, a specific etiology of Lyme disease should be sought in children who present with these symptoms in endemic areas. Facial palsy should always raise the diagnostic possibility of Lyme disease. Children with facial palsy should be assessed for meningitis and the need for lumbar puncture, especially when there is neck stiffness or severe headache.⁸² If a lumbar puncture is performed and shows CSF pleocytosis consistent with meningitis, treatment should consist of an antibiotic administered intravenously rather than orally.

Because Lyme meningitis and enteroviral meningitis are common in Lyme disease–endemic areas, it is important to appreciate characteristic clinical and laboratory features of each, in the absence of an erythema migrans rash. The presentation of Lyme meningitis is more indolent.^{27,80} Children with Lyme meningitis often experience several days of headache, lethargy, and neck pain symptoms before seeing a physician. Evidence of meningismus, such as Kernig and Brudzinski signs, is less pronounced. The CSF pleocytosis consists predominantly of mononuclear cells (mostly lymphocytes), compared with the relative prominence of neutrophils early in the course of viral meningitis. In one study, the negative predictive value for Lyme meningitis was 99% when neutrophils composed more than 10% of the cells in the CSF.⁸⁰ Clinical prediction algorithms based on these features have been developed to help in the diagnosis of Lyme meningitis.^{8,20} One of these was termed the “rule of 7s.”²⁰ Children with meningitis in whom all three of the following were present: 7 or more days of headache, 70% or more mononuclear cells, and presence of seventh (or other) cranial nerve palsy, had a 77% likelihood of Lyme meningitis, while absence of all of these predictors was highly sensitive (96%) for identifying a low risk for Lyme meningitis. Another important difference between Lyme meningitis and viral meningitis is the more frequent complication of increased intracranial pressure that is associated with Lyme meningitis. This is important because such elevated intracranial pressure is sometimes associated with transient or permanent loss of vision.^{63,72} Almost all published reports of raised intracranial pressure in Lyme disease have been in children, and the complication has been observed in the absence of meningitis.^{45,90} Headache is prominent in these children. It is important to examine the optic discs of every child with acute disseminated Lyme disease for papilledema even though this is a rare complication. Opening CSF pressure should be measured as part of the lumbar puncture, and if elevated, treatment to lower intracranial pressure should be initiated immediately.

Other neurologic signs or symptoms are very uncommon in children. Bannwarth syndrome, a neurologic manifestation of Lyme disease in Europe, consists of inflammation of peripheral nerves.⁶⁵ It should be considered in children who have recently traveled to Europe or Asia and present with neuralgia, paresthesia, and motor or sensory impairment, mostly affecting cervical and thoracic dermatomes. A true association of Lyme disease with optic neuritis, Guillain-Barré–like syndrome, or acute meningoencephalitis in published reports is very uncertain.

Carditis

Lyme carditis is a rare early dissemination manifestation of Lyme disease. It usually occurs in association with involvement of the skin and nervous system but may be the sole manifestation, presenting with syncope and malaise. Abnormalities include first-, second-, or third-degree atrioventricular conduction block or bundle branch block.^{32,36} An electrocardiogram should be considered in a child with acute disseminated Lyme disease because cardiac conduction abnormalities are often asymptomatic. Rare presentations of Lyme carditis are myocarditis, myopericarditis, left ventricular dysfunction, or cardiomegaly. Patients with Lyme carditis almost invariably have positive *B. burgdorferi* serology acutely or at follow-up.⁵ The outcome in children who receive appropriate antibiotic therapy for Lyme carditis is excellent.

Acute Generalized Illness

Investigators in Connecticut tested the hypothesis that early Lyme disease can present with a nonspecific illness without focal manifestations. Five of 24 untreated children who presented to their primary care physicians with “flu-like illness” of less than 3 weeks’ duration without identifiable cause were found to have serologic evidence of acute *B. burgdorferi* infection.²⁸ Less than 10% of children with *B. burgdorferi* infection are estimated to present in this way. Antibiotic treatment

should not be prescribed for children with nonspecific illness without *B. burgdorferi*–specific laboratory confirmation of Lyme disease. Because babesiosis, human granulocytic anaplasmosis, ehrlichiosis, and *Borrelia miyamotoi* infection can have a similar generalized clinical presentation, these infections also should be considered in evaluating any child thought to have tick-borne illness who presents with nonspecific findings.⁴⁸

Borrelia mayonii Infection

Six patients (three children and three adults) were described in the initial report of *Borrelia mayonii* infection. All resided in Minnesota, North Dakota, or Wisconsin. Disease manifestations differed from those of *B. burgdorferi* *sensu lato* because all presented with prominent constitutional symptoms, and some patients had diffuse macular rash or lymphopenia, thrombocytopenia, or elevated hepatic transaminases. All patients had a high level of spirochetemia. Five were treated with doxycycline and one with ceftriaxone. Infection resolved in all the patients without complications.⁶⁸

Late Disseminated Disease

Arthritis

Arthritis develops as the first symptom of Lyme disease weeks to months after the tick bite. The mean incubation period is about 4 months.¹⁰² Arthritis usually presents in children who do not receive appropriate antibiotics for acute Lyme disease because the tick bite or rash goes unnoticed. Many children report intermittent and migratory arthralgias or mild periarticular inflammation in the weeks leading up to development of frank arthritis. Lyme arthritis presents as a monoarthritis in two-thirds of cases and as an oligoarthritis (fewer than four joints) in the remainder.³⁵ The knee is the most common presenting joint and is involved in 90% of the cases. There usually is obvious joint swelling and effusion with greater stiffness than expected, given mild to moderate associated pain. Children most often continue to walk and are not immediately taken for emergency care. It is not unusual for the swelling to be attributed to an acute traumatic event and for a child to be initially evaluated by an orthopedic surgeon. These clinical features distinguish Lyme arthritis from septic arthritis (which usually presents in a more fulminant manner), despite similar laboratory findings of neutrophil-predominant exudate in synovial fluid and elevated acute phase reactants. An effusion typically reaccumulates if arthrocentesis is performed, consistent with the pathogenesis of a reactive arthritis. Active inflammation persists for several weeks even after appropriate treatment. Both the severity and duration of arthritis are increased in adolescents.⁴¹ Recurrent episodes can involve the same joint or a different joint, another pattern that is consistent with reactive arthritis.

Late Neurologic Disease

Follow-up studies of children who previously had Lyme disease have demonstrated an excellent neuropsychological outcome.¹ Low-grade encephalopathy and sensorineural peripheral neuropathy have been described infrequently as late sequelae of Lyme disease in adults. In contrast, late neurologic disease is rarely, if ever, encountered in children. Occasionally, cognitive disorders, processing deficits on neuropsychological tests, or persistent fatigue in children are erroneously attributed to Lyme disease. Even if *B. burgdorferi* antibodies are detected in a child with these symptoms, this is almost always evidence of previously resolved infection that is unrelated to neurologic symptoms. There is very little evidence that incidentally detected nonspecific white matter changes on magnetic resonance imaging of the brain are due to Lyme disease. Assays of CSF for culture, *B. burgdorferi* DNA, antibody, or antigen detection are not useful in children with suspected *B. burgdorferi*–induced neurologic disease because they have very poor specificity and sensitivity.³⁷

Other Manifestations

Asymptomatic Seroconversion

Asymptomatic seroconversion refers to the development of antibodies to *B. burgdorferi* infection in the absence of a recognized illness. This is well documented and common in endemic areas.⁴⁷ The ratio of symptomatic infection to asymptomatic Lyme disease was about 9:1 in a prospective study in an endemic area.⁹⁹ Children remain well, indicating successful clearance of the spirochete rather than latent

infection. There is no evidence that children with asymptomatic seroconversion should be treated with antibiotics if they have continued to be well at the time of this diagnosis.

Acrodermatitis Chronica Atrophicans

ACA is a late chronic skin manifestation of Lyme borreliosis that occurs in Europe.⁵⁹ The lesions are painful, blue-red discolored areas of swelling on the extremities, usually accompanied by a sensory peripheral neuropathy. Although rarely encountered in children, it is important to include ACA in the differential diagnosis of discolored skin lesions so that atrophic and neural sequelae can be minimized by early treatment.¹¹⁰

Borrelial Lymphocytoma

Borrelial lymphocytoma is a localized manifestation of disseminated Lyme disease that is seen in Europe. It mimics a benign tumor of the skin, usually on the earlobes or breast areolae.²¹ The lesion is a painless solitary blue-red plaque or nodule 1 to 5 cm in diameter, which develops 1 to 6 months after the tick bite (Fig. 140.2E).

Coinfection With Other Ixodes Tick-Borne Pathogens

Human babesiosis and human granulocytic anaplasmosis (HGA) are tick-borne diseases that may be cotransmitted with *B. burgdorferi* in areas where these infections are endemic. Between 3% and 13% of Lyme disease patients may experience babesiosis or HGA coinfection, or both, in areas where these infections are endemic.^{23,48,50,76} Coinfection with babesiosis or HGA is associated with an increase in acute symptoms compared with Lyme disease alone and may result in a more extended period of illness. Physicians caring for patients with moderate to severe Lyme disease should consider obtaining diagnostic tests for babesiosis and anaplasmosis in regions where these diseases are zoonotic. This is especially important when the response to antibiotic treatment is inadequate. There are no data indicating that Lyme disease complications are increased as a result of coinfection.

Lyme Disease in Pregnancy

There has been concern that untreated Lyme disease during pregnancy could result in fetal or neonatal disease, even though maternal-to-fetal transmission appears to be very rare, if it occurs at all. Large epidemiologic investigations have failed to show an association between mothers' exposure during pregnancy and fetal death, prematurity, or congenital malformations.^{34,100,101} To date, there have been no proven cases of *B. burgdorferi* causing fetal wastage, fetal malformations, or persistent neonatal infection.^{25,55}

DIAGNOSIS

Most persons who acquire Lyme disease do not recall a tick bite because the tick is small, the bite is painless, and the tick falls off after feeding. Lyme disease is primarily diagnosed by clinical manifestations, most commonly an erythema migrans rash, with supportive epidemiologic evidence, and laboratory confirmation for manifestations other than erythema migrans. The CDC developed a clinical case definition for Lyme disease that was initially intended for epidemiologic surveillance purposes. When used in conjunction with the US Food and Drug Administration (FDA) guidelines for diagnostic tests, this case definition has been widely accepted as a way to standardize the clinical diagnosis of Lyme disease. A patient is considered to have Lyme disease by the CDC case definition if they have an erythema migrans rash, or at least one objective sign of early disseminated or late disease (musculoskeletal, nervous, or cardiovascular signs), in addition to a positive laboratory test result that confirms infection with *B. burgdorferi*. Laboratory testing is not required or recommended for a patient who has erythema migrans.

Erythema migrans is defined as a skin lesion that begins as a red macule or papule and expands over a period of days to weeks to form a large round lesion, often with partial central clearing. For CDC surveillance purposes a single primary lesion must reach at least 5 cm in size. Epidemiologic evidence includes visiting a wooded, brushy, or grassy area where Lyme disease is endemic, 1 to 32 days before onset of the rash. A deer tick bite at the site of the rash may or may not have been identified. Positive *B. burgdorferi* serology is not necessary for

the diagnosis of erythema migrans. Early disseminated neurologic manifestations include cranial neuritis (particularly facial palsy) or lymphocytic meningitis, alone or in combination. Encephalomyelitis must be confirmed by demonstration of antibody production against *B. burgdorferi* in the CSF with a higher titer of antibody in the CSF than in the serum. Early disseminated cardiovascular system manifestations include acute onset of a high-grade second- or third-degree atrioventricular conduction defect that resolves in days to weeks and is sometimes associated with myocarditis. Late musculoskeletal manifestations consist of objective joint swelling in one or a few joints.

Serology is the primary laboratory test used to confirm the diagnosis of Lyme disease because unlike most other bacterial illnesses, Lyme disease is very seldom diagnosed by culture, polymerase chain reaction (PCR), or microscopic visualization of the organism.^{52,109} Antibodies to *B. burgdorferi* begin to develop during early localized infection. The immune response intensifies in patients with early disseminated or late disease.⁵ A patient with erythema migrans may become *B. burgdorferi* antibody positive during therapy. This does not constitute treatment failure because approximately one-fourth of patients with erythema migrans are antibody positive when diagnosed and an additional one-half become positive during therapy. In contrast to syphilis where a falling VDRL titer indicates successful therapy, *B. burgdorferi* antibodies may remain elevated for years in a successfully treated patient. Serial *B. burgdorferi* serology should not be used to monitor effectiveness of treatment of Lyme disease.

A two-tier approach is recommended for the detection of antibodies to *B. burgdorferi*.^{5,17} The first test consists of one of several FDA-approved enzyme-linked immunosorbent assay (ELISA) tests for total immunoglobulin M (IgM) and IgG antibodies to the antigens of *B. burgdorferi* spirochete. The ELISA is a very sensitive assay, and false-positive results are common, primarily from cross-reacting antibodies against microorganisms that share antigenically similar proteins with *B. burgdorferi*. Therefore sera that are positive or equivocal by ELISA are then tested using separate IgM and IgG Western immunoblot assays to confirm the ELISA results. The Western immunoblot is more specific than the ELISA because it identifies antibodies in the patient's serum to individual polypeptides of *B. burgdorferi*. They are visualized and reported as "bands" according to their molecular weight expressed in kilodaltons (kD). Based on extensive laboratory testing, the CDC has defined a positive *B. burgdorferi* IgM immunoblot result as the presence of at least two of three following bands: 23, 39, and 41 kD. A blot for IgG is considered positive if at least five of the following 10 bands are present: 18, 23, 28, 30, 39, 41, 45, 58, 66, and 93 kD.¹⁷ Only the IgG response should be used to support the diagnosis after the first month of infection. After that time, an IgM response alone is very likely to represent a false-positive result.⁷⁹ Immunoblot interpretation should only be performed in qualified laboratories that follow CDC-recommended evidence-based guidelines on immunoblot interpretation. The use of immunoblot alone for diagnosis of Lyme disease is not recommended.

As with any diagnostic test, the predictive value of serologic tests for Lyme disease depends on the probability that the patient has Lyme disease, based on epidemiologic and clinical history and the physical examination (the "pretest probability" of Lyme disease). Use of serologic tests to "rule out" Lyme disease in patients with a low probability of the illness will result in a very high proportion of test results that are falsely positive.⁴³ Therefore antibody tests for Lyme disease should not be used as screening tests, as has become common practice in children with nonspecific fevers, arthralgias, headaches, or fatigue. Even in areas with a high prevalence of Lyme disease, patients with only nonspecific signs and symptoms are not likely to have Lyme disease.^{30,83} Physicians should avoid requesting *B. burgdorferi* serology on such patients because they have a very low pretest probability of disease and false-positive results cause patient anxiety, unnecessary antibiotic treatment, and the possibility of missing another diagnosis.³⁰

Patients with erythema migrans should not have serologic testing because they frequently are seronegative at this early stage of the infection, and a typical erythema migrans rash is pathognomonic for Lyme disease. If the rash is atypical, the patient is not treated, and serology is negative or equivocal, a second specimen should be obtained within 2 to 4 weeks. Patients with early neurologic manifestations of Lyme disease have

demonstrable serum antibodies to *B. burgdorferi*, but the response may be limited to IgM antibodies.^{20,42} Patients with Lyme carditis almost always have positive *B. burgdorferi* serology acutely or at follow-up.^{4,5} Patients with Lyme arthritis invariably have positive *B. burgdorferi* serology for IgG antibodies.⁵ The presence of a positive serologic result does not guarantee that a medical condition is due to *B. burgdorferi* infection, however, because the positive serology may be due to previous infection or to a false-positive test result. The background *B. burgdorferi* seropositivity in areas that are highly endemic for Lyme disease may exceed 4%.⁴⁹

Additional tests to confirm *B. burgdorferi* infection in clinical specimens have been used primarily in research settings. For CSF, these include measurement of CSF-to-serum antibody ratios to document specific intrathecal antibody production, *B. burgdorferi* DNA detection by PCR testing, and *B. burgdorferi* culture of CSF, skin biopsies, and joint fluid.¹⁰⁹ Because of limited availability, expense, poor sensitivity, and insufficient evidence of value in the management of most patients, these tests should be reserved for special situations in which the pretest probability of Lyme disease is high but manifestations are atypical. Tests to detect antigens of *B. burgdorferi* in urine are not FDA approved, and they have no current role in the diagnosis or management of Lyme disease.

TREATMENT AND PROGNOSIS

The current standard for treatment of Lyme disease in children is the evidence-based Infectious Diseases Society of America Practice Guideline.¹⁰⁶ Treatment recommendations are listed in Table 140.2, and selected treatment principles are discussed here. *Borrelia burgdorferi* is highly susceptible to β -lactam antibiotics and tetracyclines. Consequently, treatment of Lyme disease is effective at all stages of the infection, and treatment failures are very uncommon. First-line antibiotics are β -lactams or doxycycline, the latter drug being effective for treatment of HGA (although not for babesiosis) that may simultaneously occur with Lyme disease.

Doxycycline and amoxicillin are equivalent choices for treatment of early Lyme disease. Doxycycline usually is prescribed for children 8 years or older and amoxicillin for children younger than 8 years. Ceftriaxone is the treatment of choice for early disseminated Lyme disease presenting as meningitis or advanced atrioventricular heart

block. If a child presenting with Lyme facial palsy is assessed for concomitant meningitis, presence of CSF pleocytosis would suggest the use of parenteral ceftriaxone rather than an oral antibiotic. Children experiencing carditis who have second- or third-degree atrioventricular block and those with first-degree heart block when the PR interval is prolonged to 30 milliseconds or longer should be hospitalized and continuously monitored. This is because the degree of block may fluctuate and worsen very rapidly. Patients experiencing advanced heart block should have a consultation with a cardiologist. A temporary pacemaker may be required. Fortunately, cardiac arrhythmias and heart block due to Lyme disease usually resolve within a few days.

Children with Lyme arthritis are treated with doxycycline or amoxicillin. For those who have persistent or recurrent joint swelling after antibiotic therapy, retreatment with a 4-week course of oral antibiotics or with a 2- to 4-week course of ceftriaxone should be considered. If persistent synovitis is associated with significant pain or limitation of function, nonsteroidal antiinflammatory agents, intraarticular corticosteroids, disease-modifying antirheumatic drugs such as hydroxychloroquine, or arthroscopic synovectomy provides symptomatic relief.¹⁰⁴ Ongoing knee pain is often due to patellofemoral joint disease rather than arthritis.

The prognosis for children given appropriate antibiotic therapy for Lyme disease is excellent. This includes children with arthritis, even though recurrent episodes of arthritis can occur.¹⁰⁴ In one study, parents were telephoned 2 to 12 years after their child had experienced Lyme disease. Four of 90 children had ongoing musculoskeletal complaints, but none had evidence of arthritis.³⁵ The incidence of chronic arthritis was higher in children in Germany, where about half of 55 children treated for a previous diagnosis of Lyme arthritis had chronic arthritis either at onset or during their follow-up.⁹¹ A poorer outcome was associated with older age and female gender.

Despite resolution of the objective manifestations of Lyme disease, children on rare occasions may continue to experience fatigue, musculoskeletal pain, or difficulties with concentration or short-term memory. There is no evidence that these are attributable to persistent *B. burgdorferi* infection.⁸⁵ The pathogenesis of these symptoms is not well defined but is probably similar to other postinfectious conditions in which persistent immune-mediated inflammation occurs in the absence of active infection. There is no evidence that prolonged courses of antibiotic treatment that exceed 1 month are effective for adults with

TABLE 140.2 Treatment of Lyme Borreliosis

Manifestation	First-Line Drugs	Alternate Drugs	Second-Line Drugs
Early localized erythema migrans	Amoxicillin PO 14 days or doxycycline PO 10 days	Cefuroxime axetil PO ^a 14 days	Azithromycin PO 7–10 days
Multiple erythema migrans	Amoxicillin PO 14 days or doxycycline PO 10 days	Cefuroxime axetil PO ^a 14 days	Azithromycin PO 7–10 days
Facial palsy or spinal radiculopathy	Amoxicillin PO 14 days or doxycycline PO 14 days		Azithromycin PO 7–10 days
Meningitis	Ceftriaxone IV 14 days or cefotaxime IV 14 days	None, although trials in Europe demonstrated efficacy of doxycycline PO	
Cardiac ^b	Amoxicillin PO 14–21 days or doxycycline PO 14–21 days or ceftriaxone IV 14–21 days or cefotaxime IV 14–21 days		
Arthritis	Amoxicillin PO 28 days or doxycycline PO 28 days		
Persistent arthritis after course of oral therapy	Retreat with one of above oral regimens	Ceftriaxone ^c IV 14–28 days or cefotaxime ^c IV 14–28 days	
Asymptomatic seroconversion or acute constitutional illness	Amoxicillin PO 14 days or doxycycline PO 14 days		Azithromycin PO 7–10 days

^aCefuroxime axetil was tested in children age ≥ 12 years.

^bFirst-degree block with PR interval <0.3 s, PO therapy; PR >0.3 s or higher grade, IV initially then PO if there is a rapid response.

^cFor oral therapy failures only.

IV, Intravenously; PO, orally.

Doses:

- Doxycycline PO 2–4 mg/kg/day divided into 2 doses, up to adult dose of 100 mg twice a day.
- Amoxicillin PO 50 mg/kg/day divided into 3 doses, up to adult dose of 2 g/day.
- Cefuroxime axetil PO 30 mg/kg/day divided into 2 doses, up to adult dose of 500 mg twice a day.
- Azithromycin 10 mg/kg once daily, up to 500 mg/day.
- Ceftriaxone IV 100 mg/kg/day once daily, up to adult dose of 2 g/day.
- Cefotaxime IV 180 mg/kg/day, up to adult dose of 2 g q8h.

ongoing symptoms after Lyme disease, based on at least four prospective controlled antibiotic trials.^{12,30} There also are no data to suggest that children differ from adults in this regard. As with adults, it is not appropriate to prescribe an antibiotic for a child who has positive serology in the absence of accompanying or recent specific clinical manifestations. The term *chronic Lyme disease* has been used by a small number of practitioners to describe patients whom they believe have persistent *B. burgdorferi* infection, a condition they suggest requires long-term antibiotic treatment and may even be incurable.³⁰ The assumption that chronic, subjective symptoms are caused by persistent infection with *B. burgdorferi* is not supported by carefully conducted laboratory studies or by controlled treatment trials.⁷

PREVENTION AND MANAGEMENT OF Ixodes TICK BITES

Prevention of Tick Bites

It is obviously best to keep free of tick-infested vegetation such as brush and wooded areas, but recreational, occupational, and residential habits make it difficult to avoid tick exposure for most people living in endemic areas.³⁸ Ticks are often present in grassy areas and in leaf litter on personal property and can attach during even brief exposure. Use of repellents is very helpful in preventing tick bites. Light-colored clothes (to make crawling ticks more visible), long-sleeved clothing, and socks tucked or taped into pants are somewhat effective, and more so if used in conjunction with repellents. The repellent DEET (N,N-diethyl-m-toluamide, or N,N-diethyl-3-methylbenzamide) is the most effective but is underutilized because of exaggerated concerns about potential toxicity. Very little DEET is absorbed after topical application, and it is rapidly metabolized and eliminated. In very young children care should be taken to avoid application near mucosal surfaces. Certain DEET-sunscreen combinations and topical retinoids can enhance the absorption of DEET, however, and the use of combination DEET-sunscreen preparations is not recommended.^{46,71} A 30% formulation provides about 6 hours of protection. The use of higher concentrations has been discontinued in Canada. Permethrin is a highly effective acaricide and repellent that can be applied to or impregnated in clothing, shoes, and fomites and affords additional protection.⁴⁶

Tick checks under bright lighting should be performed at the end of each day of exposure. Use of a washcloth or tweezers with special attention to armpit, groin, back, and scalp areas may dislodge unattached ticks. Studies have demonstrated that early removal of an *Ixodes* tick minimized the risk for acquiring *B. burgdorferi* infection.^{60,93}

The geographic range of *Ixodes* tick species is expanding beyond previously endemic regions, and practitioners should be knowledgeable about the incidence of Lyme disease where they practice. Most Lyme disease occurs in the peridomestic environment. Landscape-management measures, such as keeping grass mowed, removing leaf litter, using plantings that do not attract deer, deer fences, spraying areas of high tick density with acaricidal formulations, and using dry pebble or wood chip borders between lawns and surrounding vegetation may help reduce the risk for tick-borne infections.³⁸ The elimination of deer populations sharply reduces the risk for infection but is difficult to implement. Public education about the risks and characteristic symptoms of tick-borne diseases is an important component of prevention.

Preventing Infection After an Ixodes Tick Bite

The risk for acquiring *B. burgdorferi* infection following an *Ixodes* tick bite is low, even in endemic areas. The incidence was 1.2% to 4.4% in US studies.^{3,22,84} Nevertheless, considerable apprehension accompanies tick bites, and practitioners tend to overprescribe antibiotic prophylaxis.⁶⁴

The use of an evidence-based approach will serve to allay anxiety, decrease indiscriminate use of antibiotics, and prevent some cases of *B. burgdorferi* infection. A tick should be removed with an ordinary pair of thin-tipped tweezers or forceps. The tick should be grasped by the mouth end and gently pulled straight upward. There is no evidence that residual embedded mouth parts or crushing the tick increase risk for transmission. Other removal techniques are ineffective and can be dangerous.⁶² Most important, the patient should save the tick in any

dry vessel for identification because almost one-third of suspected deer ticks are a different species or not ticks at all.⁹³ By referring to images on the Internet, a practitioner should be able to distinguish a six-legged insect from an eight-legged tick, differentiate a dog tick or a Lone Star tick from a deer tick, and differentiate a nymphal from an adult female deer tick.⁸⁹ Most commercial laboratories and health departments in endemic areas perform tick identification. Patient requests to have a tick analyzed for *B. burgdorferi* DNA should be discouraged because this testing may be unreliable and does not correlate with transmission risk. More important are the developmental stage of the tick and the duration of attachment. Most cases of Lyme disease are transmitted by nymphal deer ticks.⁶⁰ Duration of attachment is critical because there is a 36- to 72-hour delay between the onset of feeding and the migration of spirochetes from the tick midgut to saliva and transmission to the host. The incidence of infection increases 20-fold for ticks attached for 72 hours or longer compared with those attached for less than 72 hours.⁹³ Tick identification and assessment of engorgement can be used to help define a small, high-risk subset of people who should benefit from antibiotic prophylaxis.

A single dose of doxycycline was shown to be 87% effective in prevention of Lyme borreliosis in a study in a Lyme disease hyperendemic area of the United States, where an *I. scapularis* tick was analyzed within 72 hours of the bite and duration of attachment of 72 hours was documented by an entomologist.⁶⁰ Adverse effects occurred in 30% of doxycycline recipients, however. If the tick species, stage, and duration of attachment cannot be determined, a “wait and watch” approach is appropriate, given the overall low risk for Lyme borreliosis. This is the standard approach in Europe.⁹⁴ Serologic testing does not benefit management decisions after a tick bite and is not recommended. In sum, routine use of antibiotics to prevent Lyme disease in persons who are bitten by a deer tick is not recommended, even in highly endemic areas. Persons who have removed attached ticks from themselves can submit the tick for identification and should be monitored closely for signs and symptoms of Lyme disease (and other tick-borne diseases) for up to 1 month. Those who develop a rash at the site of the tick bite or multiple skin lesions elsewhere, or a generalized nonspecific illness, should promptly seek medical attention.

Relapsing fever is an arthropod-borne infection caused by several species of spirochetes in the genus *Borrelia*.^{*} Two major types of relapsing fever are classified according to their arthropod vector, tick-borne (TBRF) relapsing fever and louse-borne (LBRF) relapsing fever. TBRF may further be classified into soft tick-borne relapsing fever (STBRF) and hard tick-borne relapsing fever (HTBRF). Each category of arthropod vector transmits a different *Borrelia* species or group of species, but all cause relapsing fever (Fig. 141.1). Illness is characterized by recurring episodes of fever and nonspecific symptoms that include headache, shaking chills, myalgia, arthralgia, and abdominal distress, separated by periods of well-being or minor symptoms.^{22,24,53} The characteristic relapse of symptoms is caused by recurrent spirochetemia and the associated immune responses. After a *Borrelia* relapsing fever strain infects a person, its proliferation in blood is curtailed by antibody and other immune factors. The *Borrelia* subsequently change surface antigens so that a new variant (serotype) emerges and the cycle is repeated.^{2,4,5,46,56,65} A single organism can produce as many as 40 antigenic variant membrane proteins, and six or more relapses may occur over several months.²² The clinical presentation is highly variable, with some patients experiencing a viral-like illness, some gastrointestinal symptoms, and others meningitis or meningoencephalitis.¹⁶ Although the disease may be severe, the fatality rate in treated STBRF patients is less than 5%.²³ The fatality rate for treated LBRF patients is about 5%; however, it may exceed 40% in large LBRF epidemics among nutritionally and immunosuppressed populations caught up in war or famine.^{11,23,63} During the last great LBRF epidemic in North Africa and Europe during WWII, an estimated 50,000 patients died of the illness.^{11,23,27} Both HTBRF and LBRF occur worldwide, but only LBRF is currently confined to northern Africa and Europe (through refugees).

ORGANISM

Borrelia are spirochetal bacteria whose spiral shape enhances their motility and whose loose coiling helps distinguish them from other spirochetes such as *Leptospira* and *Treponema* (Fig. 141.2).^{6,26,34,72} They have inner and outer membranes and several internal flagella that are not surface exposed. The flagella are responsible for shape and motility. *Borrelia* spp. are divided into two major groups: the Lyme borreliosis group that are transmitted exclusively by hard-bodied ticks, and the relapsing fever group that are primarily transmitted by soft-bodied ticks but also by hard-bodied ticks and lice.^{6,26,72}

The genome of the STBRF spirochete relapsing fever *Borrelia hermsii* contains a linear chromosome of about 1 million base pairs and one copy each of several types of linear and circular plasmids. There are 5 to 10 identical genomes in each organism.^{5,6} Numerous surface lipoproteins of the outer membrane called *variable major proteins* (Vmps) determine variant or serotype identity.² A change in the expression of Vmps allows the relapsing fever *Borrelia* to survive in the highly diverse environments of mammal and tick and allows the organism to escape immune attack within mammalian hosts.^{2,3,4,5,46,50,56,65} The HTBRF *Borrelia* (*Borrelia miyamotoi*) genome consists of a linear chromosome of about 1 million base pairs and eight complete linear plasmids. It also contains incomplete plasmids, including up to five putative incomplete circular plasmid and one linear plasmid.⁷⁴

Relapsing fever *Borrelia* are microaerophilic and can be cultivated in cell-free media but have complex nutritional requirements for growth.^{6,72} They may no longer be able to infect laboratory animals after several passages in vitro and may lose their ability to infect ticks after prolonged passage in laboratory animals.

TRANSMISSION

Relapsing fever is transmitted in almost all cases by an infected tick or louse (see Fig. 141.1). Rare causes of transmission include blood transfusion, intravenous drug use, laboratory worker accidents, and transplacental transmission from mother to fetus.^{6,28,64,72}

Currently, most reported cases of relapsing fever are transmitted by soft-bodied (*Ornithodoros*) ticks. Transmission begins within minutes of the start of a blood meal that takes from 15 to 90 minutes.^{6,23} The ticks usually feed at night, and most relapsing fever patients are unaware of being bitten. The *Borrelia* and the ticks are maintained in a tick-mammalian host life cycle in which rodents and other small mammals become asymptotically infected and provide a blood meal for the ticks.^{22,23,26} Nymphal and adult ticks are the most common source of transmission, but in some tick species larvae may be infected through transovarial transmission whereby an adult female transmits infection to her eggs.²³ Humans are a dead-end host for TBRF and do not contribute to the transmission cycle. The recently discovered HTBRF *Borrelia* (*Borrelia miyamotoi*) has been found in hard-bodied (ixodid) ticks in North America and Eurasia.^{29,51,62} About 15% of the spirochetes found in *Ixodes scapularis* (the tick vector for Lyme disease, babesiosis, and anaplasmosis) are *B. miyamotoi*.⁶²

LBRF occurs when an infected louse feeds on a human, the sole known host.³⁶ In contrast to TBRF, humans are the reservoir host for LBRF and are responsible for perpetuating the infection cycle. Transmission occurs when the louse is wounded or crushed by scratching and infected hemolymph or feces contaminate the bite site. LBRF is most common when large numbers of people gather in one area and hygiene is compromised.

EPIDEMIOLOGY

Twelve different species of *Borrelia* have been shown to cause TBRF (Table 141.1).⁶ In the United States, the most common species is *Borrelia hermsii* followed by *Borrelia turicatae* and *Borrelia parkeri*.^{6,23} Cases are reported most frequently from California, Washington, and Colorado.⁷⁵ Cases most commonly occur in the summertime among people who have slept in rustic cabins or caves in forested areas.^{1,8,17,18,19,67,68} TBRF is very widespread outside the United States, and cases have been described in Canada, Mexico, Central and South America, Africa, Asia, and Europe.^{1,23} Human cases of *B. miyamotoi* relapsing fever have been described in the United States, Europe, and Asia. The discovery of this spirochete in a variety of ixodid ticks greatly expands the potential geographic distribution of relapsing fever, and it is likely that *B. miyamotoi* will be found wherever Lyme disease is endemic.^{30,39,33,21,40,58,35,43,51,62} In contrast, LBRF is caused by a single species of *Borrelia*, *Borrelia recurrentis*. It has been found worldwide but is currently only significantly endemic in Ethiopia and Sudan.^{53,54} Cases have been reported from European countries in recent years among refugees from North Africa.^{76,77}

PATHOGENESIS AND PATHOLOGY

Relapsing fever *Borrelia* enter the bloodstream after tick transmission and rapidly multiply. Based on animal experiments and human studies with LBRF and STBRF, it is estimated that bacterial concentrations reach 100,000 to 1 million spirochetes per milliliter of blood during symptomatic disease.^{11,23,65} This accounts for their characteristics visualization on Wright-stained peripheral blood smears (Fig. 141.2).^{8,76} *Borrelia* are initially phagocytized in the bloodstream by neutrophils, macrophages, and dendritic cells that cause the release of cytokines and other immune

*References 6, 11, 22–24, 26, 27, 32, 34, 36, 41, 54, 72.

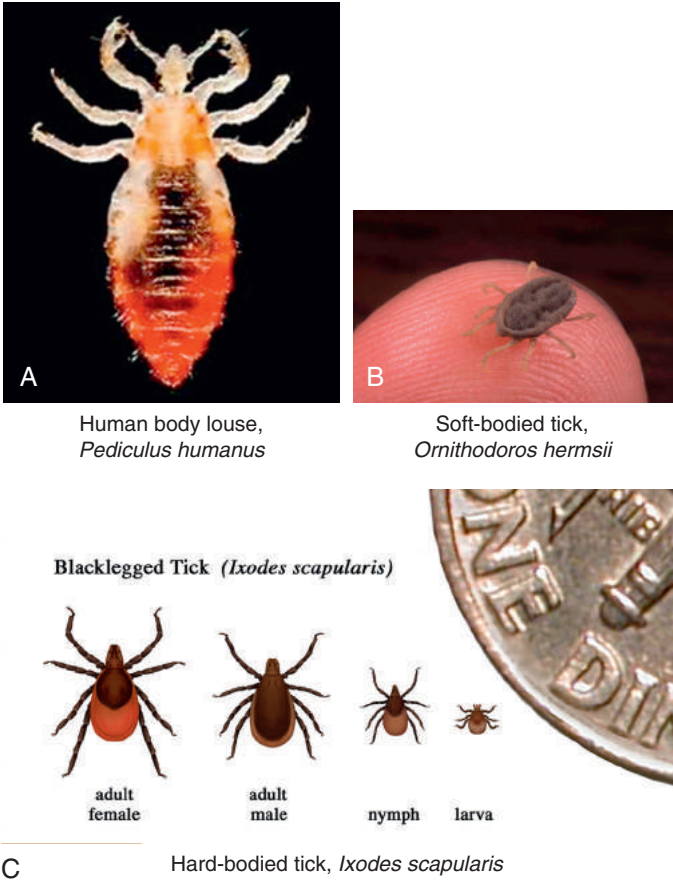

FIG. 141.1 Examples of vectors of relapsing fever. (A) Louse-borne relapsing fever (human body louse *Pediculus humanus*). (B) Soft tick-borne relapsing fever (*Ornithodoros hermsii*). (C) Hard tick-borne relapsing fever (*Ixodes scapularis*). (From Centers for Disease Control and Prevention. https://www.cdc.gov/relapsing_fever/symptoms/index.html.)

FIG. 141.2 *Borrelia hermsii* spirochetes in the peripheral blood smear of a patient with tick-borne relapsing fever (Wright stain, $\times 1000$). (From Centers for Disease Control and Prevention. https://www.cdc.gov/relapsing_fever/symptoms/index.html.)

factors, resulting in symptoms.^{13,15,52,70,73} Antibody (especially immunoglobulin M [IgM]) plays a central role in bacterial eradication, and most *Borrelia* are cleared from the bloodstream after 2 to 3 days.^{23,65} Surviving *Borrelia* are able to change outer membrane proteins so that the original IgM antibodies are no longer effective. A new antigenic variant emerges and causes recurrence of fever and other symptoms.^{2-5,38,46,56,59,65} The same process repeats itself for several cycles in untreated patients. Because there is some antibody cross-reactivity, subsequent spirochetemia and clinical manifestations usually are milder.⁹ *Borrelia* antigenic variation is a result of new outer surface Vmps that are encoded by alternative *vmp* genes found on linear plasmids.^{2-5,59} There is a copy of silent and expressed genes on the same or different plasmids within each borrelial microorganism. Antigenic switching occurs when a silent *vmp* gene

TABLE 141.1 Important *Borrelia* Causing Relapsing Fever, Their Vectors, and Their Current Geographic Distribution

Borrelia Species	Vector	Geographic Distribution
Louse-Borne Relapsing Fever		
<i>B. recurrentis</i>	<i>Pediculus humanus humanus</i>	Ethiopia, Sudan
Soft Tick-Borne Relapsing Fever		
<i>B. caucasica</i>	<i>Ornithodoros verrucosus</i>	Iraq, central Russia
<i>B. crocidurae</i>	<i>Ornithodoros erraticus</i> (small variant)	North Africa, Middle East
<i>B. duttonii</i>	<i>Ornithodoros moubata</i>	Eastern and Central Africa
<i>B. hermsii</i>	<i>Ornithodoros hermsi</i>	Western United States and Canada
<i>B. hispanica</i>	<i>Ornithodoros erraticus</i> (large variant)	Spain, western North Africa
<i>B. latyschewii</i>	<i>Ornithodoros tartakowskyi</i>	Iran, central Asia
<i>B. mazzottii</i>	<i>Ornithodoros talaje</i>	Mexico, Central America
<i>B. parkeri</i>	<i>Ornithodoros parkeri</i>	Western United States
<i>B. persica</i>	<i>Ornithodoros tholozani</i>	Middle East, western Asia
<i>B. turicatae</i>	<i>Ornithodoros turicata</i>	Southwestern United States, Mexico
<i>B. venezuelensis</i>	<i>Ornithodoros rudis</i>	Northern South America
Hard Tick-Borne Relapsing Fever		
<i>B. miyamotoi</i>	<i>Ixodes scapularis</i> , <i>Ixodes pacificus</i> , <i>Ixodes ricinus</i> , <i>Ixodes persulcatus</i> ,	Northeastern, northern Midwestern, and Pacific Coast United States; central Russia, Europe, Japan

begins to encode for protein while the existing *vmp* gene is shut down. The stimulus for antigenic switching is unknown. Recent data suggest that the antigenic switching that occurs when relapsing *Borrelia* move from mouse to tick is induced by the temperature change from the warm-blooded host to the cooler tick vector.⁵⁹

Relapsing fever *Borrelia* are not confined to the bloodstream but also infect the nervous system, eyes, lung, liver, kidney, heart, and spleen.^{20,23,24,27,36} They may persist in these tissues.⁶ There is evidence in animal models that the same serotype antigenic variation that is seen in the blood also occurs in brain tissue, where *Borrelia* have been shown to persist for up to 3 years.⁶ Tissue damage in fatal human cases has been noted in the central nervous system (meningitis, degenerative lesions, hemorrhage, and perivascular infiltrates), heart (myocarditis), lung (pneumonia), gastrointestinal tract (hemorrhage), liver (enlargement, hepatic necrosis), and spleen (splenic abscess).^{27,36} Relapsing fever *Borrelia* can cross the placenta or be transmitted during birth, causing abortion, premature birth, or severe perinatal infection.^{28,64}

CLINICAL MANIFESTATIONS

Initial clinical manifestations may consist of the characteristic recurring fever and accompanying symptoms of headache, chills, and fatigue or may reflect rapid dissemination to the central nervous system, gastrointestinal tract, or lungs.* Symptom type and severity depend on the species and strain of infecting *Borrelia* and the age and immune status of the host. Although TBRF and LBRF have similar clinical manifestations, tick-borne illness generally is less severe (Table 141.2). *B. recurrentis* (LBRF) and *Borrelia duttonii* (STBRF) are associated with severe disease. Pregnant women often experience severe disease.^{22,28,64}

TABLE 141.2 Characteristics of Tick-Borne Relapsing Fever and Lyme Disease

Characteristic ^a	FREQUENCY	
	Tick-Borne Relapsing Fever	Lyme Disease
Fever relapses	Common	Rare/none
Fever $\geq 39^{\circ}\text{C}$	Common	Rare
Focal skin rash	Rare/none	Common
Arthritis	Rare/none	Common
Neurologic involvement	Occasional	Occasional
Spirochetes on blood smear	Common	Rare/none
Jarisch-Herxheimer reaction	Common	Occasional

^aClinical characteristics of untreated patients in the United States.

FIG. 141.3 Examples of relapsing fever episodes in two patients with *Borrelia miyamotoi* infection. Arrows indicate the timing of tick bite, hospital admission, polymerase chain reaction (PCR) testing, anti-*Borrelia* immunoglobulin M (IgM) testing, and initiation of antimicrobial drug therapy. (From Platonov AE, Karan LS, Kolyasnikova NM, et al. Humans infected with the relapsing fever spirochete *Borrelia miyamotoi*, Russia. *Emerg Infect Dis.* 2011;17:1816-1823.)

For STBRF, the mean incubation period is 7 days, with a range of 4 to 18 days. Symptoms generally last 3 to 6 days (range, 12 hours to 17 days) for the first episode in untreated patients. This is followed by a week (range, 3 to 36 days) of well-being or mild nonspecific symptoms before the next febrile episode (Fig. 141.3).²³ The duration of symptoms and asymptomatic intervals are several days longer for LBRF. As many as six relapses have been noted in TBRF patients, but the average number is three to five in untreated patients.^{8,22,23,51} The duration of symptoms decreases and the time between relapses increases with each episode, although this is not always the case.⁶⁷

STBRF may be associated with fatal hypotension and shock, usually at the end of the first episode of fever. Gastrointestinal manifestations such as nausea, vomiting, diarrhea, hepatomegaly, or splenomegaly occur

in more than one-half the cases; dry cough in about one-fourth of cases; a macular, papular, or petechial rash in about one-fifth of cases; and meningitis in about 3% of cases.^{22,23} Ocular manifestations are seen in less than 10% of STBRF patients and include eye pain, photophobia, and conjunctival injection. Pregnant women are subject to more severe disease with high fever and associated miscarriage and congenital infection.

The clinical presentation of HTBRF is similar to that of STBRF. The typical presentation consists of fever that may exceed 140°C, fatigue, headache, myalgia, arthralgia, and chills. Relapses were reported in 11% of the first cases from Russia reported by Platonov et al. (Fig. 141.3).⁵¹ Other symptoms included nausea, vomiting, and neck stiffness.^{43,51} Meningoencephalitis has been reported in immunocompromised people.^{30,33,78}

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A history of travel to wooded areas, especially rustic cabins or caves with exposure to small rodents and ticks, is helpful in making the diagnosis of STBRF, whereas residence in or travel to a Lyme disease-endemic area is required for diagnosis of hard HTBRF. A definitive diagnosis of STBRF or LBRF generally is made by examination of a Wright-stained thick or thin blood smear (see Fig. 141.2). Use of a buffy coat smear using Giemsa stain, acridine orange stain, or darkfield examination increases diagnostic sensitivity.⁶¹ *Borrelia* are rarely found during afebrile periods.

An initial enzyme-linked immunosorbent assay (ELISA) or immunofluorescent antibody (IFA) assay followed by an immunoblot test is often used to test for antibody in acute and convalescent sera.^{40,55,60} Serology testing is compromised by alternating outer surface protein (antigenic switching) and by cross-reactivity of relapsing fever *Borrelia* antibody against other spirochetes, such as the causative agents of Lyme disease and syphilis. Glycophosphoryl diester phosphodiesterase (GlpQ) protein (produced with recombinant DNA technology) has been identified in relapsing fever spirochetes but not in the Lyme disease or syphilis spirochetes.⁶⁰ GlpQ protein-based ELISA assays are superior to those that use whole-cell preparations of cultured bacteria such as *B. hermsii*.⁶⁰ Other tests that have been developed to diagnose TBRF include *B. hermsii* and *B. miyamotoi* polymerase chain reaction, in vitro cultivation, or amplification of organisms by mouse inoculation followed by microscopic visualization.^{37,51,69}

TBRF and LBRF are frequently misdiagnosed. The differential diagnosis is broad and includes enterovirus infection, dengue, hepatitis, influenza, leptospirosis, malaria, and typhoid fever. Other tick-borne illnesses need to be considered, including anaplasmosis, babesiosis, Colorado tick fever, ehrlichiosis, Lyme disease, and Rocky Mountain spotted fever. Periodic fever syndromes such as PFAPA (periodic fever, aphthous ulcers, pharyngitis, and adenitis), hyper IgD syndrome, and familial Mediterranean fever have longer intervals between febrile episodes.^{23,42,47}

TREATMENT

Several antibiotics have been shown to be effective in treatment of relapsing fever, including doxycycline, tetracycline, erythromycin, penicillin, and chloramphenicol.^{7,44,48,49,57} For older children, doxycycline or tetracycline are the antimicrobial therapies of choice. Erythromycin is the drug of choice for children younger than 8 years because penicillin is probably less effective, doxycycline and tetracycline are associated with teeth staining, and chloramphenicol may suppress the bone marrow. For older children, doxycycline or tetracycline are the antimicrobial therapies of choice. A proposed management approach for febrile children is to substitute oral phenoxymethyl penicillin (a single low dose of 7.5 mg/kg) or intravenous penicillin G (10,000 U/kg infused over a period of 30 minutes) as initial treatment on the first day in order to minimize the potential problem of the Jarisch-Herxheimer reaction.^{12,56,70} Patients with this reaction experience an acute exacerbation of symptoms following the first dose of antibiotic.^{10,12,14,25,45,66,71} Data suggest that large numbers of bacteria are abruptly fragmented and killed with antibiotic therapy, exposing antigen that elicits an intense cytokine response. Penicillin may result in less rapid destruction of spirochetes than tetracycline or doxycycline. In one large study, 54% of patients treated for

STBRF experienced the Jarisch-Herxheimer reaction, with more than one-half experiencing high fever ($\geq 40^{\circ}\text{C}$), chills, rigors, diaphoresis, and hypotension.²³ Associated symptoms are even worse with LBRF. Fortunately, children generally experience milder reactions than adults. Regardless, they still should be monitored closely for the first 12 hours after the initial dose of antibiotic in the emergency department or hospital with intravenous access in place. Therapy consists of supportive measures, such as volume expansion and antipyretics. A 10-day course of oral erythromycin (40 mg/kg per day divided every 6 hours, maximum 500 mg/dose) or doxycycline (4 mg/kg per day divided every 12 hours, maximum 100 mg/dose) should then be given to eradicate tissue spirochetes and prevent relapse. Preventive measures for STBRF include the use of doxycycline tick bite prophylaxis and acaricidal spraying of tick-infested bedding and sleeping areas.^{8,31}

Therapy for HTBRF is the same as for Lyme disease, specifically doxycycline, amoxicillin, and ceftriaxone (for meningococcalitis).^{30,33,43,51,79} HTBRF can be prevented by avoiding areas where ticks, deer, and mice are known to thrive, using protective clothing, applying diethyltoluamide, checking for and removing ticks, managing landscape (keeping grass mowed, clearing leaf litter, spraying property with acaricides), and reducing the number of deer.⁷⁹

Leptospirosis

Delma J. Nieves

Leptospirosis is considered an emerging zoonosis due to increased contact between animals and humans and the resulting human encroachment into wildlife habitat. Climate changes of global warming and environmental shifts can affect the degree of transmission. Early detection is important to prevent morbidity and mortality most effectively. In June 2012, leptospirosis was reinstated as a Nationally Notifiable Condition in the United States. This has aided in further investigation of incidence, distribution, and risk factors associated with human cases.¹¹² Worldwide research efforts continue to dedicate additional resources and improve understanding of this fascinating organism, which continues to contribute to human morbidity and mortality. Thus far, leptospirosis is far from controlled.

HISTORY

Weil²⁸⁶ is credited with providing the first description of leptospirosis in 1886, although it had likely been previously described under various names.²⁴⁴ Not until 1915, however, was the causal agent, originally known as *Spirochaeta icterohaemorrhagiae*, identified by Inada and associates.¹²⁶ Eight years earlier, Stimson²⁴² unknowingly had identified the same organism within sections of kidney obtained from a patient in whom yellow fever had been diagnosed incorrectly.

Inada and associates demonstrated the role of the rat as a carrier in 1916.¹²⁶ Noguchi¹⁸² first recovered this organism from a Norway rat in 1917. Although the etiology of Weil syndrome in British Army troops in Flanders was found to be spirochetes and a possible connection with rats was suspected, the route of acquiring infection was not understood. In 1922, *Leptospira icterohaemorrhagiae* was isolated from the blood of a laboratory worker who developed jaundice after an accidental needlestick containing the serum of an infected rat.²⁸¹ For many years the rat was

considered the only animal host of *L. icterohaemorrhagiae*. Then, in 1944, Randall and Cooper¹⁹⁷ isolated this agent from a naturally infected dog, and *L. icterohaemorrhagiae* subsequently has been associated with many animal hosts, including goats, swine, cattle, and hamsters.

In 1938 and 1939, Meyer and associates¹⁶³ popularized the concept that infection with *L. canicola* caused disease in dogs and humans in the United States. “Canicola fever” first was reported in Great Britain in 1946²⁰; in 1951, 40% of the dogs in Great Britain were noted to be seropositive.⁴⁵ Surveys have confirmed the presence of *L. canicola* infection in species other than dogs.^{220,271}

In 1950, Gochenour and colleagues¹⁰³ identified *L. pomona* as the agent responsible for leptospirosis in cows. Widespread *L. pomona* infection among cattle in the United States was recognized quickly, and in time this finding stimulated extensive epidemiologic investigations in livestock. Infections of cattle with *L. hebdomidis* and *L. grippotyphosa* were identified, and, concomitantly, infections of swine and horses with *L. pomona* were documented.¹²¹ In Europe, *L. pomona* was identified as the agent responsible for “swineherd disease,” and it was recovered from other domestic animals as well. In 1951, the first human cases of *L. pomona* infection were identified.

Many new serotypes of leptospires were recognized in the early 1950s after the establishment of serologic diagnostic services for leptospires by the Centers for Disease Control and Prevention (CDC) and the Walter Reed Army Institute of Research. Along with the identification of additional leptospiral serotypes, the spectrum of clinical disease associated with infection by leptospires was elucidated. Patients with autumnal fever (a disease in Japanese peasants and potters) and Fort Bragg fever (a febrile illness associated with pretibial eruptions described in army recruits) were shown to suffer from leptospirosis caused by *L. autumnalis*.^{102,212} “Mud fever,” “pea-pickers disease,” and “European swamp fever,” names

that were used to describe a disease of undetermined etiology in eastern Germany, the Far East, and western Poland, respectively, were shown to be examples of leptospirosis caused by *L. grippotyphosa*.⁵¹ Seven-day fever in Japan, Wycon fever and Bushy Creek fever in the United States, cane field fever in Australia, and swineherd disease in Europe were identified as examples of infection caused by *L. hebdomidis*, *L. canicola*, *L. pomona*, *L. australis*, and *L. pomona*, respectively.^{26,32,39,63,121}

Leptospirosis is a disease now thought to be caused by a single family of organisms that has multiple serogroups and serotypes⁴ and is characterized by a broad spectrum of clinical findings.¹⁹⁰ More than 300 strains, called serovars (serotypes), which are divided into serogroups on the basis of common antigens, have been identified. These are divided into two species: *L. interrogans* sensu lato, which contains the pathogenic strains; and *L. biflexa* sensu lato, which contains the saprophytic strains.¹¹⁸ Using a newer classification based on DNA relatedness, the genus *Leptospira* can be classified into 22 species. Identified thus far are 10 species of pathogenic *Leptospira*, five intermediate species that may cause mild clinical manifestations, and seven saprophytic species that are environmental but do not cause disease in humans or animals.³⁸ Serovars of the same group may be distributed between different species.⁵⁴ Leptospirosis is now often described as the most widespread and prevalent zoonotic disease worldwide. The organism's ability to survive outside the host as well as establish a chronic carrier state in rodents promotes its survival and promulgation. Global warming and increased rainfall are predictors of increased incidence. In 2003, the World Health Organization (WHO) reported a worldwide incidence of 0.1 to 1 case per 100,000 population per year in temperate climates, more than 10 cases per 100,000 population in humid subtropical region, and more than 100 cases per 100,000 population during outbreaks.¹¹⁸ However, the difficulty in diagnosing and identifying chronic infection leads to underestimation.³ Traxler and colleagues analyzed US hospital discharge records for 1998–2009 and estimated an annual rate of leptospirosis-associated hospitalizations of 0.6 per 1 million population. But this is just the peak of the iceberg in terms of describing the true incidence of leptospirosis in the United States, where national surveillance ceased from 1994 to 2013.²⁵⁹ Outbreaks in poor urban slums with rat infestations have contributed to its title as a neglected infection of poverty in the United States.¹²² It is also considered an infection of adventure seekers with outdoor recreational exposure and international travel.^{145,185,215} WHO established the Leptospirosis Burden Epidemiology Reference Group (LERG), which is focused on better estimating the global burden of disease.²⁹¹ In September 2015, LERG published findings from a systematic literature review of the data on leptospirosis morbidity and mortality, estimating annually 1.03 million cases and 58,900 deaths due to leptospirosis worldwide.⁶⁷

EPIDEMIOLOGY

Animal Reservoirs

Among mammals, rodents are the most important reservoir of leptospires, but nearly all mammals may be infected and can transmit the disease.²⁵⁷ Leptospire also have been isolated in reptiles and birds, but the epidemiologic significance of these animals in terms of maintenance of the organism in nature or transmission of disease to humans is not clear. For many species, infectivity rates of 10% to 50% have been reported frequently.^{121,200} During epizootics, the circulation of leptospires among many species of animals (including rats, cows, dogs, swine, mongoose) living within a given biocenosis has been well recognized.^{19,71,130,166,210,217}

The failure of leptospires to elicit a significant systemic antibody response in certain animal species may be due to the development of local immunity within their kidney tubules.^{21,250} Some animals fail to develop homologous antibody titers but harbor leptospires in their kidneys for extended periods.²⁵⁰ Thus lack of a positive titer to leptospires, as determined during the course of serologic surveys of animal populations, does not indicate absence of infection, leaving the true incidence of infection unknown.

A particular host species may serve as a reservoir for one or more serotypes of leptospires, and a particular serotype may be hosted by many different animal species. Turner^{264,267} stressed that a particular animal species commonly serves as a reservoir for selected serotypes but temporarily may be infected and serve as an incidental host for other serotypes with which it usually is not infected.

Transmission of Leptospire to Humans

Leptospire are transmitted to humans either by contact with blood, urine, tissues, or organs of infected animals or by exposure to an environment that has been contaminated by leptospires. Humans usually represent a dead end in the chain of infection because although person-to-person transmission is possible theoretically, it is rare. After direct exposure of humans to infected animals, leptospires may enter breaks in the skin or may penetrate the mucous membranes, including the conjunctiva, nasopharynx, and vagina.^{26,74,211,267} Human-to-human transmission via human milk has been reported in a breast-fed infant from a lactating mother who was infected with *L. interrogans*.³⁶

Indirect transmission of leptospires to humans (from soil or water) depends on the presence of an environment that favors the survival of leptospires outside the animal host. A warm climate (25°C [77°F]), the presence of moisture, and pH values of soil or surface water between 6.2 and 8.0 are optimal conditions for survival of leptospires. These conditions prevail in many tropical regions throughout the year and in temperate climates during the late spring, summer, and autumn. Smith and Self²³¹ demonstrated survival of leptospires in cultures of infected soil for 43 days. In a survey of leptospirosis in Hawaii from 1999 to 2008, among 177 cases where exposure was determined, 45% were from recreational exposure (freshwater swimming, hiking, camping), 44% were occupational (taro farming), and 11% were from exposure around the home (gardening).¹³⁸ A study of human leptospirosis in the Caribbean from 1997 to 2005 found that in cases of suspected leptospirosis the highest seropositivity was found among 1- to 20-year-old and 31- to 40-year-old males, and its occurrence was higher during the wet season.⁵ Ingestion or exposure from contaminated water sources, such as through infected rat or cattle urine, is a well-described source of leptospirosis in humans.^{47,101,267} The importance of occupation as related to the risk for leptospirosis was emphasized in 1965.¹²¹ Disease appeared to occur most frequently in people with occupations that required exposure to cattle or swine or to water contaminated by rat urine. The urine of infected cows may contain as many as 100 million leptospires per milliliter. If conditions are favorable, surface water contaminated by the urine of infected cattle may remain infectious for several weeks.⁴⁸ The largest reported outbreak of leptospirosis in the United States occurred in 1998 in Springfield, Illinois, after a triathlon that was preceded by heavy rains. There were 66 laboratory-confirmed cases of leptospirosis after the event, which included a swimming portion in a lake that received runoff from nearby livestock farms. Fifty-two of these cases occurred in triathlon participants, and 11 cases involved nonparticipants who came in contact with lake water near the event.¹⁷⁰ In a study performed in Detroit, 90% of rats carried *L. icterohaemorrhagiae*.⁷⁷ Strain-specific tests comparing antibody titers in the sera of inner-city and suburban children were performed. Thirty-one percent of inner-city children had antibodies against *L. icterohaemorrhagiae*; 10% of suburban children also had antibodies to this organism. Lau and colleagues have studied the patterns of global climate change, flooding, and urbanization to predict that an increase in leptospirosis can be expected.¹⁴⁴

Venereal transmission of leptospirosis is important in rodents and can occur in livestock. Leptospire have been recovered from the semen of bulls and have been transmitted by artificial insemination and by coitus. The possibility of seminal transmission in humans remains speculative. Transplacental infection of the fetus in utero is well documented in livestock and other animals and may occur in humans.^{50,59,60,64,74,265,267}

During the past several decades, the number of cases acquired during outdoor recreation has increased. In developed countries, an increasing percentage of cases of leptospirosis are from travelers returning from areas of high endemicity and are often related to water activities.¹⁴⁵ In California, from 1982 to 2001, 59% of reported cases of leptospirosis were due to recreational exposure (often to contaminated freshwater), increasing to 85% in the 1997 to 2001 period.¹⁶¹

The dog, including the immunized pet dog, has been incriminated as an important vector and as a reservoir of leptospirosis.^{106,249} Although immunization of dogs against leptospirosis is possible, it is important to remember that (1) immunization may not prevent the dog from having renal carriage and excreting the organism, (2) canine immunity after immunization may wane after just 1 year, and (3) immunity, when established, is effective only for serotypes present in the canine vaccine.²¹

In one survey of suburban and urban areas, however, between 15% and 40% of dogs were found to be infected.³¹ Harkin and coworkers found that irrespective of health status, 8.2% of dogs were shedding pathogenic leptospires.¹¹⁷ Rojas and colleagues found that 7.05% of dogs had urinary shedding.²⁰⁴ Dogs were implicated in 58% of the 820 known cases of leptospirosis reported between 1962 and 1971.⁵³

Asymptomatic renal colonization in humans has been shown. Using a 16S rDNA hybridization assay technique to identify *Leptospira* DNA in urine, Ganoza and associates identified a long-term renal shedder group (interestingly all women) among persons asymptotically infected with pathogenic and intermediately pathogenic *Leptospira*. Almost 5% of healthy people living in a rural Amazonian community were urinary shedders of *Leptospira* but did not have serologic or clinical evidence of recent infection.⁹⁹ It is not understood if this could play a role in human-to-human transmission or some subtle degree of kidney disease.

A recent review of the literature found that a large proportion of cases (48%) and deaths (42%) were estimated to occur in adult males 20 to 49 years of age, and the highest estimates of disease morbidity and mortality were observed in the Global Burden of Disease regions of South and Southeast Asia; Oceania; Caribbean, Andean, central, and tropical Latin America; and east sub-Saharan Africa.⁶⁷ Another study estimated that globally approximately 2.90 million disability-adjusted life years are lost per annum from the approximately annual 1.03 million cases.²⁵⁶ A study reviewing the literature and focusing specifically on African countries reported that acute human leptospirosis ranged from 2.3% to 19.8% in hospital patients with febrile illness.¹⁰

PATHOPHYSIOLOGY

After almost 100 years since the discovery of the causative organism of leptospirosis, the understanding of mechanisms of pathogenesis has come a long way. Leptospires are thin and highly motile spirochetes with two periplasmic flagella responsible for their movement.⁸⁸ They have a double-membrane structure, making it unique and similar to both gram-positive and gram-negative bacteria. Describing the membrane from inside out, leptospires have an inner cytoplasmic membrane, a peptidoglycan cell wall, periplasm, outer membrane with outer-membrane proteins (OMPs), phospholipids, and lipopolysaccharide (LPS).^{69,70}

The era of genomics with the data generated by the *Leptospira* Genome Project has provided new insights into potential virulence factors as well as host response to disease.^{148,155,176} Valuable information has been obtained by the use of animal models of acute and chronic disease, by observing the interactions of leptospires with various cell lines, and by employing molecular genetic tools. Because of their inherent ability to revolve rapidly in a corkscrew fashion, it had been suggested in early studies that the organism bores through connective tissue.²³⁸ Since then, the specific factors responsible for invasiveness of leptospires have been extensively studied and are better understood.^{85,95,240} In vitro studies have shown that leptospires bind to a wide range of extracellular matrix components. They have been shown to bind to several different cells, including endothelial cells, monocytes, macrophages, kidney epithelial cells, and fibroblasts.⁴³ They can translocate through polarized MDCK cells, suggesting a possible intracellular component to its life cycle.²⁷ Goeijenbier and colleagues found that plasma level of soluble E (sE)-selectin and von Willebrand factor (VWF) was strongly increased in patients with severe leptospirosis, sE-selectin was significantly elevated in survivors, endothelial cells exposed to virulent *Leptospira* showed increased VWF expression, and soluble Fas-ligand and soluble interleukin-2 (IL-2) receptor were strongly associated with mortality.¹⁰⁵ These findings show that endothelial cell activation and immune activation were associated with disease severity in leptospirosis patients. Pathogenic *Leptospira* may inhibit the activation of the complement system through the secretion of proteases that cleave and inactivate key complement proteins.⁹⁶ The ability of spirochetes to interact with the host fibrinolytic system may contribute to the degradation of the extracellular matrix components, immune evasion, and tissue penetrations and invasion.²⁷⁵

Leptospiral immunoglobulin-like proteins (Lig), surface proteins found in pathogenic leptospires, are believed to be involved in cell adhesion⁹² and are among those that have been studied as potential

vaccine candidates.¹⁶⁹ Lig-bound plasmin was shown to cleave fibrinogen and the complement proteins C3b and C5, which may allow for invasion and complement immune system evasion by *Leptospira*.⁵²

Specific factors responsible for the virulence of leptospires, although better understood, still remain unclear. Some of these virulence factors that continue to be a subject of investigation include LPS, hemolysins, OMPs, surface proteins, and adhesion molecules.⁸⁵ An animal model of disease showed caspase-3 reactive renal epithelial cells, alveolar cells, and liver cells, suggesting that *L. interrogans* induce activation of apoptosis in later phases of the infection process.¹⁵³ The completion of the *Leptospira* genome sequence has revealed several proteins suspected to play a role in pathogenesis.^{7,61,198} Comparative analysis of *Leptospira* proteomes looking at different serovars of pathogenic organisms, nonpathogenic organisms, clinical isolates, and acute lethal infection versus chronic carrier infection has elucidated potential virulence factors and vaccine candidates.^{61,69,180,181,254} Hemolysin-like proteins have been identified, including sphingomyelinases that are present in pathogenic but not saprophytic leptospires. Surface-exposed proteins that might have potential roles in adhesion and pathogenesis include OmpL36, OmpL37, OmpL47, and OmpL54.¹⁹¹ OmpL1 displayed significant adhesin activity binding to glycosaminoglycans and monolayers of human cells in vitro and may be a promising component for a subunit vaccine.²⁰³ The outer surface proteins LigA, LigB, and LigC contain immunoglobulin-like domains¹⁵⁶ found in virulence factors such as intimin and invasins. Leptospiral endostatin-like proteins (Len) have been identified that have been shown to be involved in the organism's ability to evade the complement system.²⁴⁰

LipL32 is the major OMP of *Leptospira* shown to bind collagens, laminin, and fibronectin and is highly conserved in pathogenic species.^{114,120,263} It is the most abundant protein in the cell and is highly immunogenic.²⁸⁰ LipL32 stimulates a strong antibody response during natural infection, yet vaccination studies using LipL32 have yielded mixed results.¹⁷⁵ A study of *Leptospira* from urine of infected rats showed acetylation or trimethylation of the highly abundant LipL32 in comparison with culture-grown *Leptospira*, which did not result in a lysine modification, suggesting that LipL32 modifications may alter protein recognition by the immune response, perhaps contributing to bacterial persistence during infection.²⁹⁰

Loa22 is a lipoprotein that is upregulated during acute infection and appears to be necessary for virulence in animal models of disease.^{181,202} However, the specific roles and functions in pathogenesis for many of these molecules are not entirely understood. A significant amount of redundancy in functional virulence proteins is suspected.

The possible role played by animal hosts in determining the virulence of leptospires for humans remains speculative. Faine⁸⁶ compared the fate of virulent and nonvirulent strains of *L. icterohaemorrhagiae* in guinea pigs. Both strains behaved similarly after intraperitoneal infection, but virulent organisms survived and multiplied, whereas avirulent strains did not. Both virulent and avirulent strains were taken up by fixed phagocytes in reticuloendothelial tissues in vivo. Faine⁸⁷ also showed that the severity of lesions correlated positively with the number of organisms present and that a discrete number of organisms were required to cause death. He hypothesized that virulence results from the selective multiplication of virulent leptospires in vivo. This hypothesis was supported by the fact that maximum virulence can be regained after a single animal passage that follows isolation in culture. Virulence may be lost in culture by mutation to nonvirulent forms.

The humoral response is the main mechanism of resistance against leptospirosis. Immunoglobulin G (IgG) and IgM antibodies are detected in patients who have recovered from infection. Antibodies are produced against leptospiral LPS. LPS vaccines are effective, but immunity is limited to homologous serovars.⁸⁵ Wang and associates²⁸³ demonstrated that polymorphonuclear leukocytes are not an efficient defense factor for pathogenic leptospires in nonimmune hosts. The virulence of leptospires appears to be related to their ability to resist killing both by serum and by neutrophils.

A toxic and pathogenic potential in vivo for lipid products of leptospiral metabolism has been suggested.² The cell wall of the leptospire is high in lipid content; component fatty acids vary among leptospiral strains. Lipids are used as a source of energy by leptospires.² Saprophytic leptospires invariably possess lipase activity, whereas pathogenic

leptospire may be lipase positive or lipase negative.² Kasarov and Addamiano¹³⁷ investigated the lipolytic activity of leptospire on serum lipoproteins. On the basis of their ability to attack these lipoproteins, leptospire can be divided into three groups: (1) strains that degrade lecithin and sphingomyelin, (2) strains that degrade neither lecithin nor sphingomyelin, and (3) strains that degrade lecithin but not sphingomyelin. Virulent leptospire behaved as group 1 and 2 strains, whereas saprophytic leptospire behaved as a group 3 strain.

Pathophysiology as seen and understood of the clinical disease processes seen in leptospirosis is outlined in **Box 142.1**. Hemolytic anemia, jaundice, hepatic and renal injury, pulmonary injury, and cardiovascular, nervous system, ocular, and musculoskeletal findings have been extensively studied and described.

CLINICAL MANIFESTATIONS

Leptospirosis is an acute systemic infection characterized by extensive vasculitis. Serologic surveys in human populations indicate that a large number of subclinical infections also occur. Surveys of veterinarians and packinghouse and abattoir workers reveal positive leptospiral titers

in 5% to 16% of people tested.^{131,165,171,255} A low index of suspicion for this disorder by physicians, coupled with the diversity and nonspecificity of its manifestations, accounts for the significant number of cases that go unrecognized. In one series of 483 proven cases, only 17% were diagnosed initially as leptospirosis.³²

The incubation period generally is 7 to 12 days, but a range of 2 to 20 days has been noted.^{216,238,266} The incubation period does not vary significantly among serotypes and is not of prognostic significance. Variability in incubation period may be attributed to the dose of virulent organisms to which the host is exposed and to the portal of entry of the organism.^{216,238,266}

The clinical course of leptospirosis varies, but generally it is predictable: both anicteric leptospirosis and icteric leptospirosis follow a biphasic course (**Fig. 142.1**).

The first stage (septicemic phase) is characterized by acute systemic infection. The onset of symptoms is abrupt. This phase terminates after 4 to 7 days; symptomatic improvement and defervescence coincide with disappearance of leptospire from the blood, CSF, and all other tissues, with the exception of the aqueous humor and renal parenchyma. Antibody titers to leptospire develop rapidly; this immune response

BOX 142.1 Pathophysiology of Specific Clinical Findings in Leptospirosis

Hemolytic Anemia, Jaundice, and Hepatic Injury

- Presence of a hemolysin in the supernate of leptospiral cultures^{9,30,123,172,206}
- Cloned hemolysin of *L. interrogans* serovar Lai demonstrated cell membrane pore-forming activity in vitro¹⁴⁷
- Thrombocytopenia, depletion of serum prothrombin, depletion of host vitamin K^{51,62,81,110,196,201,283}
- Capillary injury perhaps by toxin¹⁵
- Hemorrhage of skin or mucosal surfaces and rarely gastrointestinal or into a vital organ¹¹⁰
- Hepatic manifestations, including jaundice, most likely are the result of hepatocellular injury^{14,15,34,81,196,281}
- Hemolysis possibly contributing to jaundice^{81,253}
- One or more toxins by leptospire or release of various products after lysis possibly injuring hepatocytes^{16,109,198}

Renal Injury

- Tubular epithelial cell necrosis, acute vasculitis, segmental thickening of basement membrane, and interstitial edema
- Infiltrates of lymphocytes, monocytes, plasma cells, and neutrophils
- Cells lining the lumen of the renal tubules distended, disorganized, and contain hyaline, granular, epithelial, and bile casts
- Glomeruli showing mesangial hyperplasia, focal fusion of foot processes, swelling of the epithelium in Bowman capsule, and thickening of the basement membrane^{14,16,59,66,76,125,142,229,292}
- Renal potassium wasting by increased secretion of aldosterone and cortisol¹
- Tubulointerstitial nephritis the most common lesion associated with chronic infection^{14,125}
- Leptospire demonstrated in the liver, renal tubules, and the interstices of the renal cortex^{14,81,142}
- Leptospire evading the renal immune system, including absence of complement, downregulation of antigens, delayed lymphocyte infiltration, and delayed colonization of renal tubules^{167,168}
- Impaired renal blood flow leading to nephropathy^{15,16,34,66,81,84,146}
- Host response to infection possibly inducing damage as B cells and T cells induce inflammation in the liver and kidneys via a TLR-independent pathway^{108,194,287,288}

Pulmonary Involvement

- Pulmonary lesions generally the result of hemorrhage rather than acute inflammation^{17,189,226,293}

- Leptospire visualized directly in lung parenchyma²²⁶
- Alveolar septal deposition of immunoglobulin and complement^{76,179,218,293}

Cardiovascular Findings

- Hypovolemia or hypotension from dehydration, bleeding, or third spacing^{18,81,93,189,293}
- Vascular collapse seen with adrenal insufficiency secondary to hemorrhage¹⁴⁷
- Hypoperfusion, focal hemorrhagic myocarditis, acute coronary arteritis, pericarditis, aortitis, cardiac arrhythmias, congestive heart failure, hypertension, hypovolemia, electrolyte imbalance, or uremia^{14,75,223,234,248}
- Epicardium, endocardium, and myocardium all possibly involved^{14,15,81,109,253}

Nervous System Findings

- Meningeal reaction occurs only after the development of antibody, leptospiral meningitis suggested to be a reflection of an antigen-antibody reaction^{14,17,21,62,110}
- Uncommon features of leptospirosis include encephalitis, myelitis, radiculitis, and peripheral neuritis^{14,81,100,104,142,164}
- Neurologic manifestations attributed to subarachnoid, peripapillary, and subdural hemorrhages^{46,48}

Ocular Involvement

- Possibly direct *Leptospira*-mediated injury to eye structures, but suggestion that cross-reacting antibodies play a role in *Leptospira*-associated recurrent uveitis^{143,274}

Musculoskeletal Findings

- Myalgia an early clinical feature concurrent with leptospirosis septicemic stage, correlating with the timing of the histologic changes in muscle that often quickly resolves
- Muscle pain that subsides after leptospiral agglutinin titers develop^{35,81,129,146,224,235,253}
- Bone involvement in leptospirosis not a significant feature¹²⁷

Other

- No characteristic lesions noted in the adrenal glands, lymph nodes, spleen, gastrointestinal tract, pancreas, ureter, or bladder
- Interstitial edema with monocytic and lymphocytic infiltrates found in testicular tissue associated with impaired spermatogenesis¹⁰⁴

FIG. 142.1 Clinical course of leptospirosis: anicteric and icteric disease. CSF, Cerebrospinal fluid.

heralds the second, or “immune,” stage of the illness, which lasts 4 to 30 days. Leptospiruria is prevalent and continues for 1 week to 1 month; generally, it is unaffected by antibiotic therapy. Meningitis or hepatic or renal manifestations, when present, reach their peak intensity during this stage of the disease.

There is also a more recently described severe pulmonary form of leptospirosis that may occur in the absence of jaundice or as an elevated Weil syndrome and carries a high mortality (see later).¹⁵²

Leptospirosis manifestations in children are similar and can be very severe as well.^{58,134,135,262,273,274,276} During the 2001 outbreak of leptospirosis in Mumbai, India, 32% of children admitted in a 2-month period had leptospirosis.¹³⁵ A year earlier in the same city, following floods, leptospirosis was found in 34% of children screened who had abrupt onset of fever, contact with flood water, conjunctival suffusion, abdominal pain, or rash.¹³⁴

Anicteric Leptospirosis

Ninety percent or more of all patients with leptospirosis are anicteric. They frequently escape definitive diagnosis because jaundice and azotemia are absent. The onset of the septicemic phase of anicteric leptospirosis is abrupt⁸² and heralded by fever, malaise, headache, myalgia, and occasionally prostration and circulatory collapse.¹⁵⁸ Chills, remittent fever, headaches, severe myalgia, and abdominal pain are prominent for 4 to 7 days. Fever defervesces by lysis, and other symptoms resolve. Death is an extraordinarily rare occurrence in the first stage of anicteric illness. Some patients with anicteric leptospirosis do not experience a biphasic illness and remain asymptomatic after the first week.⁸²

The second phase of anicteric disease may be characterized by fever, uveitis, rash, headache, and meningitis. If present, fever usually is of brief duration and has a lower peak than that of the septicemic phase.^{81,82,121} Maximum temperatures range from 38.2°C to 40.6°C (100.8°F–105°F), with one or more daily peaks. Recurrence of fever 2 or 3 weeks after leptospirosis resolves is not unusual, but no reports of the isolation of leptospires from blood document relapse on these occasions. Relapse generally occurs when the immune response of the host is peaking and at a time of maximal leptospiruria, which suggests an allergic or immune basis for the febrile episodes.³⁴ Headache may be intense and usually is not controlled well by analgesics. Typically, it is frontal in distribution and characterized as bitemporal or occipital. It may be associated with retrobulbar pain.^{65,81,82} Persistence or recurrence of headache after termination of the septicemic phase of disease generally indicates the onset of meningitis. The factors responsible for headache in the septicemic phase of leptospirosis are unknown.

Restlessness, nocturnal confusion, mood disturbances, and mild alterations in consciousness usually occur briefly and commonly in both stages of leptospirosis.^{81,121} Delirium, hallucinations, psychotic behavior, and suicidal tendencies have been reported.^{81,121,222}

Anorexia, nausea, vomiting, and abdominal pain may be reported in both stages of anicteric disease. Constipation, diarrhea, and gastrointestinal hemorrhage also have been documented.^{81,158,182} Generally, hemorrhagic complications are associated exclusively with icteric disease.

Physical examination during the septicemic stage may reveal dehydration, muscle tenderness, conjunctival suffusion, generalized lymphadenopathy, hepatosplenomegaly, and rashes that may be macular, maculopapular, erythematous, urticarial, petechial, purpuric, hemorrhagic, or desquamating. Skin lesions are most prominent over the trunk, but any area of the body may be affected. Pretibial eruptions have been noted in patients with infection caused by *L. autumnalis*, but other serotypes also may cause disease with pretibial eruptions. Recurrent, transient urticarial eruptions have appeared for many days after resolution of the other manifestations of leptospirosis. Pharyngitis, rales, arthritis, and nonpitting edema occur less commonly.* Tachycardia is a common occurrence, and cardiac arrhythmias are noted occasionally.^{188,234} Hypotension rarely occurs in anicteric leptospirosis.⁸²

Muscle pain and tenderness may be generalized, but the muscles of the calf, lumbosacral spine, and abdomen are affected most frequently. Tenderness and rigidity of the abdominal wall may suggest the possibility of an acute surgical abdomen. Tenderness of the muscles adjacent to the cervical spine often causes nuchal rigidity in patients without meningeal involvement. The muscle tenderness usually subsides with termination of the septicemic stage of the disease.

Conjunctival suffusion, photophobia, ocular pain, and conjunctival hemorrhage are more specifically helpful diagnostic signs. Chemosis and inflammatory exudates generally are absent despite marked conjunctival infection. In anicteric disease, conjunctival infection involves primarily the bulbar conjunctiva only. It appears by the third day of illness and disappears 3 days to 3 weeks later.

Abdominal pain and tenderness, when associated with vomiting and hypoactive bowel sounds, clearly suggest the possibility of a surgical abdomen and present a challenging diagnostic problem because acute intraabdominal catastrophes may complicate the natural history of this disease. Nonobstructive toxic dilation of the gallbladder requiring cholecystectomy has been noted repeatedly in children with leptospirosis

*References 11, 14, 33, 65, 82, 121, 129, 158, 207, 260, 266,

FIG. 142.2 Nonobstructed toxic dilation of the gallbladder in a child with leptospirosis. Radiograph demonstrates a dilated, opaque gallbladder protruding from the inferior margin of the liver.

(Fig. 142.2). Pain of this type must be differentiated from myositis, subperitoneal or subserosal hemorrhage, abdominal wall causalgia, or pancreatitis, all of which may occur in some children with anicteric or icteric disease.

Pulmonary involvement may be observed in anicteric patients, generally during the septicemic phase, and usually is manifested as a dry, hacking cough, occasionally productive of blood-stained sputum, or by the finding of infiltrates on a chest radiograph.^{33,193,226} Hemoptysis, chest pain, respiratory distress, and cyanosis appear rarely during anicteric disease.¹⁹³ Hemoptysis, when present, clears in 3 to 5 days. Physical examination of the chest may reveal rales, evidence of consolidation, or a pleural or pericardial friction rub.

Chest radiographs may show (1) confluent infiltrates or massive consolidation representing larger areas of pulmonary hemorrhage; (2) small, patchy, snowflake-like lesions in the periphery of the lung fields that are restricted to a few intercostal spaces or disseminated widely; and (3) solitary, patchy lesions with ill-defined margins.^{193,282} Of these radiographic appearances, the second is most common. Small pleural effusions are rare occurrences in anicteric disease,²⁸² and hilar adenopathy has not been described. Although the chest radiograph may help delineate the extent of pulmonary disease, it does not provide information that could be considered pathognomonic of leptospirosis.

Other signs and symptoms of the septicemic phase of anicteric leptospirosis that have been reported include parotitis,²⁹ orchitis,²⁴³ epididymitis,¹²¹ prostatitis,¹²¹ otitis media,³³ arthralgia,^{33,81,121} and monoarticular or polyarticular arthritis.⁷⁶

The hallmark of the immune phase of anicteric leptospirosis is meningitis, and it is reflected by CSF pleocytosis with or without meningeal symptoms or signs. During the leptospiremic phase, leptospires may be found in the subarachnoid space unassociated with the presence of inflammatory cells. As an antibody titer develops, leptospires are cleared rapidly from CSF, and an inflammatory response develops.⁸¹ If CSF is examined during the second week of illness in all patients with anicteric leptospirosis, a meningeal reaction can be demonstrated in more than 80%, but only 50% of these patients have clinical signs and symptoms of meningitis.^{49,81} The severity of meningitis varies and does not correlate with the severity of other clinical manifestations of leptospirosis. Symptoms referable to the nervous system usually subside within 1 or 2 days but rarely persist for 2 or 3 weeks. The CSF pleocytosis may persist for 2 to 3 months but generally disappears within 7 to 21 days.⁸¹ In some cases, patients do not have symptoms during the

septicemic phase of leptospirosis but seek medical attention during the immune phase because of headache, vomiting, and nuchal rigidity. Papilledema rarely has been observed in patients with leptospirosis.⁴⁶

Lumbar puncture may reveal CSF pressures varying from normal to 350 mm H₂O. Mean values generally are less than 200 mm H₂O.¹²⁴ Cell counts within CSF vary from normal to more than 500 cells/mm³; generally, fewer than 500 cells have been reported.^{81,121} Polymorphonuclear leukocytes predominate early in the immune phase, but mononuclear cells subsequently predominate. Protein concentrations within CSF range from normal to 300 mg/dL. In some cases, protein values have been elevated in the absence of pleocytosis. Abnormal values may persist for several weeks after the clinical symptoms resolve.^{33,49,121,159,160} Glucose concentrations within CSF generally are normal.^{49,82,159}

Encephalitis, focal weakness, spasticity, paralysis, nystagmus, peripheral neuritis, cranial nerve paralysis, seizures, radiculitis, visual disturbances, myelitis, Guillain-Barré syndrome, or acute disseminated encephalomyelitis may appear with or subsequent to the immune stage of anicteric disease.^{12,25,55,81,84,121,159,164,272} Generally, these symptoms resolve, but complete resolution may require several weeks to months. Neurologic sequelae secondary to central nervous system hemolysis may occur.^{46,48}

The anterior uveal tract may be affected as early as the third week of illness, but symptoms may be found up to 1 year after the onset of leptospirosis. Conjunctival suffusion (characteristic during the septicemic phase) is not found in the immune stage of the disease. Rather, iritis, iridocyclitis, and, occasionally, chorioretinitis are noted.^{32,81,82,121} Uveal involvement may be unilateral or bilateral and may occur as a single, self-limited episode, as recurrent episodes, or as a chronic unrelenting process.^{41,81} The severity of the uveitis does not correlate with the severity of other clinical manifestations. When uveitis is transient or self-limited, complete healing is the rule; however, in some cases, blindness and cataract formation are noted.

The precise incidence of involvement of the uveal tract is unclear because symptoms may be minimal or may not appear until after other clinical manifestations have resolved completely. The generally benign course of uveitis may be attributable to the capacity of leptospires to survive in the aqueous humor without eliciting an intense inflammatory response.⁸² Despite the presence of high titers of specific antibodies to leptospires in serum, antibodies to leptospires are absent or found in low titer in the aqueous humor.

Leptospiuria is the rule during the immune stage of anicteric leptospirosis, and it is not associated with impaired renal function. In contrast to many animal species, humans do not serve as a reservoir for leptospires; leptospiuria is transient. In anicteric patients, proteinuria, pyuria, microscopic hematuria, and mild to moderate azotemia may be observed.³³

The white blood cell count may be low, normal, or elevated. Neutrophilia is the rule, regardless of the total white blood cell count. Leukocytosis generally is associated with hepatic involvement. Anemia is an inconsistent finding; when present, it may be attributable to blood loss, vascular damage, or hemolysis. In the absence of blood loss, significant anemia is not a manifestation of anicteric cases. The erythrocyte sedimentation rate is elevated consistently.

Icteric Leptospirosis (Weil Syndrome)

The term *Weil syndrome* should be applied to define a form of leptospirosis that is distinctive in clinical expression but nonspecific with respect to serotypic etiologic agents. In addition to having the symptoms and signs of anicteric leptospirosis, Weil syndrome is set apart by the presence of impaired hepatic and renal function, vascular collapse, hemorrhage, severe alterations in consciousness, and a high mortality rate.

Weil syndrome may be heterogeneous in its manifestations, and the course may be dominated by symptoms of renal, hepatic, or vascular dysfunction. Jaundice and azotemia may be so severe that the biphasic course of illness is not observed. Fever may persist without defervescence between the septicemic and immune stages and is more prominent and of longer duration during the immune stage than in anicteric cases. The mortality rate, despite adequate supportive care, is between 5% and 10%.

Jaundice remains the hallmark of Weil syndrome. The intensity of jaundice varies; a maximum total serum bilirubin concentration in the

range of 60 to 80 mg/dL has been reported.¹⁵⁹ Usually, the bilirubin concentration is less than 20 mg/dL. Both direct- and indirect-reacting bilirubin levels increase, but an increase in the direct fraction usually accounts for most of the elevation in bilirubin.²³⁹ Jaundice may occur as early as the third day of illness or may not appear until the second week.^{17,82} The serum bilirubin concentration peaks within the first 7 days after the onset of jaundice in 85% of cases.¹⁹⁶

Modest elevations in serum alkaline phosphatase level and depressed activity of plasma prothrombin are noted occasionally.¹⁹⁶ Hypoprotrombinemia responds uniformly to parenteral administration of vitamin K. The serum albumin level may be depressed; concentrations of 2.0 to 2.5 g are not uncommon.²³⁹ Aspartate aminotransferase and alanine aminotransferase values are elevated minimally, rarely exceeding 100 and 200 units, respectively. The urine may contain bilirubin and urobilinogen.

Hepatomegaly is found in approximately 24% of patients, a frequency that is no greater than that in anicteric cases.⁸¹ Transient biliary obstruction, probably intrahepatic, may occur, but no evidence that obstructive phenomena are the primary mechanism of impaired hepatic function exists. Even in severely icteric cases, acholic stools generally are not observed.^{81,121} Pruritus has been reported rarely in patients with leptospirosis.⁸¹ The presence of abnormal urinary urobilinogen values in the absence of acholic stools suggests patency of the biliary tract in most cases.¹⁹⁶

In some reports of children with leptospirosis, acalculous cholecystitis has been seen in 55% of cases.²⁴¹ In these patients, right upper quadrant pain, tenderness, and a palpable mass were present. Abdominal radiographs confirmed the presence of a mass in the region of the gallbladder. When cholecystotomy was performed, a massively distended gallbladder containing colorless bile was noted. Routine aerobic and anaerobic cultures of bile were negative, but cultures for leptospires were positive.

Hepatic dysfunction is not an important cause of death in patients with leptospirosis. It is present, however, in most patients who die of this disease; conversely, a fatal outcome is extremely rare in the absence of hepatic dysfunction.³³ Renal dysfunction, cardiovascular collapse, and hemorrhagic complications occur most often in patients whose icterus is most prominent.

Renal dysfunction may be observed in all forms of leptospirosis, regardless of the severity of disease or the serotype causing infection.^{33,81,121} Symptoms attributable to functional renal impairment generally are observed only during icteric leptospirosis.^{17,33,81,82,266} In the leptospiremic phase, abnormal urinalysis results are noted in as many as 80% of cases.^{33,81,241} Proteinuria is the most frequent abnormality and generally is mild. Hyaline or granular casts and cellular elements (red and white blood cells) may be found in the urinary sediment. Microscopic or gross hematuria is seen in many patients and most likely reflects the presence of a hemorrhagic diathesis rather than glomerular injury.²⁷²

Fatal cases of icteric leptospirosis in which urinalysis results were normal have been reported.¹⁷ The abnormalities in urinary sediment and proteinuria may persist for weeks in patients without significant azotemia.²⁸

Oliguria or anuria may be noted as early as the third day of illness but occurs more commonly after the first week. Generally, blood urea nitrogen values remain below 100 mg/dL, but values may exceed 300 mg/dL in some cases.^{121,183} The height of the blood urea nitrogen value is not of prognostic value in individual cases, although in groups of patients it correlates well with outcome.²⁵³

Azotemic patients with leptospirosis can be divided into two groups: (1) those with decreased renal perfusion (ratio of urine osmolality [U_{Osm}] to plasma osmolality [P_{Osm}] of about 2:1) and a good response to fluid administration; and (2) those with a U_{Osm}/P_{Osm} ratio close to 1:1, with impaired resorption of sodium and water from the renal tubules and no response to administration of fluids. The manifestations of the second group of patients are those of acute tubular necrosis. The factors responsible for oliguria in the first group of patients (those with prerenal azotemia), including hypotension, shock, and volume depletion, if uncorrected, ultimately may progress to acute tubular necrosis as well.

Anuria is an ominous sign, whereas diuresis is a good prognostic omen.¹⁷ The impairment in renal function may persist, and fatalities have been recorded after the onset of diuresis.¹⁸³ Hyposthenuria can persist for months in some cases.⁸¹ Some evidence of renal disease has

been demonstrated by renal function tests and renal biopsies for as long as 6 months after the onset of leptospirosis.²³ Renal failure is the principal cause of death in patients with leptospirosis, but it generally is reversible in time. Usually, renal function improves by 6 months after acute infection.⁷²

Cardiac involvement is a relatively infrequent occurrence, but when it is present, congestive heart failure and cardiovascular collapse may occur.^{82,129} Electrocardiographic changes are seen in all forms of leptospirosis.¹⁸⁸ In one series of patients, electrocardiograms obtained during the first week of illness were abnormal in 90% of patients at a time when none had signs or symptoms of congestive failure, pericarditis, or hypotension.¹⁸⁸ The electrocardiographic abnormalities disappeared by 10 days in most cases. The electrocardiographic changes that have been described often are nonspecific findings common to many infectious diseases or attributable to fever alone.^{188,208}

Cerebrovascular accidents may occur in patients with leptospirosis.¹⁴⁹ In a study of 21 cases in which postmortem examination was performed, subarachnoid hemorrhage was described in 1 case, cerebral hemorrhage in 2, and recent cerebral infarction in 1.

Hyponatremia is a rather consistent finding in patients with severe icteric leptospirosis. The hyponatremia appears to be the result of (1) failure of the sodium pump, which causes sodium to move intracellularly in exchange for potassium; and (2) redistribution of fluid such that the extracellular fluid space is expanded at the expense of the intracellular space. Hyponatremia in these patients may be unresponsive to either sodium replacement or fluid restriction. It is treated best by fluid restriction, which can be continued unless systemic blood pressure falls. Clinical improvement in the patient generally follows a spontaneous increase in serum sodium level, which may occur before any other evidence of clinical improvement is noted.

Most patients with leptospirosis recover without long-term sequelae.²¹⁴ However, given the evidence of prolonged urinary shedding, it has been speculated that there may be a chronic form of leptospirosis.¹²² A prospective study in São Paulo, Brazil, followed patients who had been hospitalized with leptospirosis²³⁶; two of 47 patients reported continuing symptoms, one with profound malaise without a defined reason and one with new diagnosis of panic disorder. A study²⁹⁴ in a *Leptospira*-endemic town reported that subjects with a microscopic agglutination test (MAT) titer of 400 or greater showed a decreased renal function compared to those with lower titers. And, two subjects with persistently high MAT titers and positive urine *Leptospira* DNA had worsening renal function during the study period of 2 years.

Severe Pulmonary Form of Leptospirosis

A recently described severe pulmonary form of leptospirosis may occur in the absence of jaundice or as an elevated Weil syndrome. It carries a mortality rate of greater than 50%¹⁵² and manifests as dyspnea, chest pain, and cough with hemoptysis.

The chest radiograph shows small nodular opacities that may progress into larger coalescent areas of consolidation.⁷⁸ High-resolution computed tomography shows bilateral ground-glass opacities, areas of consolidation, airspace nodules, and small pleural effusions. On gross pathology, extensive pulmonary hemorrhage with numerous bleeding foci of different sizes can be seen. Histologic sections usually demonstrate pulmonary congestion, pulmonary edema, and several foci of interstitial and intraalveolar bleeding, with varying degrees of severity.¹⁵² Treatment involves maintaining hemodynamic stability and respiratory support. Corticosteroids and platelet transfusions have been used.²²⁵ Because the pathogenesis of the severe pulmonary form of leptospirosis is thought to likely be immune mediated, immunosuppression has been used in its treatment, including plasma exchange, cyclophosphamide, desmopressin, dexamethasone, and recombinant factor.¹⁵²

INDICATORS OF PROGNOSIS

Attempts have been made to identify prognostic factors associated with leptospirosis. Such studies, which aimed to evaluate the prognostic significance of certain clinical and laboratory variables at different stages of disease, have produced variable results. Hypotension, oliguria, hyperkalemia, the development of pulmonary rales or rhonchi, and

electrocardiographic repolarization abnormalities each have been associated with a poor prognosis,^{73,79,80,151,186,252} although conflicting data exist about the implications of hypotension.⁸⁰ In a small series of 12 patients, Truccolo and colleagues²⁶¹ reported death of all patients with a leptospiral load greater than 10^4 organisms/mL as determined by quantitative polymerase chain reaction (PCR). Chang and colleagues,⁵⁷ in a series of 11 patients with late leptospirosis, reported mortality in all patients with hepatitis and a disproportionate aspartate aminotransferase level, as defined by a ratio of peak aspartate aminotransferase to peak alanine aminotransferase greater than 3. Respiratory failure, hemoptysis, metabolic acidosis, and thrombocytopenia also have been associated with increased mortality rates.²⁵² In Marotto and coworkers' prediction model, serum potassium, serum creatinine, respiratory rate, presenting shock, and Glasgow Coma Scale score less than 15 were independently associated with development of leptospirosis-associated pulmonary hemorrhage syndrome.¹⁵⁴ Advancing age, renal involvement, pulmonary involvement, and multiple organ dysfunction have been repeatedly found to be associated with increased mortality.¹⁹⁵ A case of severe leptospirosis complicated by Epstein-Barr virus reactivation has been described.¹³⁶ A case has also been described of an HIV-infected man on antiretroviral therapy and with a history of hepatitis C who developed fever and hepatitis and was found to have leptospirosis and acute or recurrence of occult hepatitis C.⁹⁰ These cases point to the need to consider concomitant infections in severe cases of leptospirosis.

LABORATORY DIAGNOSIS

Whenever possible, the physician should use laboratory facilities in which culture and serologic tests for leptospirosis are performed routinely. It is recommended that specimens be sent to the standard reference laboratory, the National Leptospirosis Laboratory at the CDC in Atlanta. Despite proper collection and handling of specimens, obtaining laboratory confirmation of cases of leptospirosis may be difficult, even for facilities with skill in this area.

A confirmed case of leptospirosis, as defined by the US Department of Health and Human Services, fulfills one of the following criteria: (1) clinical specimens that are culture positive for leptospires or (2) clinical symptoms compatible with leptospirosis and either seroconversion or a fourfold or greater rise in the MAT titer between acute and convalescent serum specimens obtained 2 or more weeks apart and studied at the same laboratory. PCR has been shown to be effective for detecting pathogenic *Leptospira* but may not be commercially available.

Presumptive leptospirosis is defined as the presence of clinical symptoms that are compatible with leptospirosis and an MAT titer of 1:100 or greater, a positive slide MAT reaction on a single serum specimen obtained after the onset of symptoms, or a stable MAT titer of 1:100 or greater in two or more serum specimens obtained after the onset of symptoms.

Identification by Culture

Leptospires can be recovered from blood or CSF obtained from patients during the septicemic stage of illness or from urine during the immune stage. Other than these body fluids, only tissue sections obtained by biopsy or at necropsy are sources from which organisms can be recovered. Rarely, organisms are isolated from intraocular fluid obtained during convalescence.⁸

Media for the cultivation of leptospires generally contain a buffered solution, with or without peptone and with or without 0.1% to 0.2% agar to which rabbit serum has been added to provide a final concentration in the medium of 5% to 10%. In addition, a pH between 7.2 and 7.8 appears to be essential. Clinical material obtained for culture frequently is contaminated; antimicrobial agents, including neomycin, vancomycin, or bacitracin, added to leptospiral media in low concentration have been found to be effective in reducing contamination and exert little if any effect on leptospires.

For routine use, Fletcher semisolid medium⁹⁴ or EMJH semisolid medium^{132,238} is recommended. Stuart medium²⁴⁵ has been used to prepare and maintain antigens for serologic tests. Tween 80–albumin medium (OAC) was developed not long ago and is available commercially. This medium seems to be superior for primary isolation of leptospires.

Several solid media are available but appear to be most useful for isolation and purification of leptospires from contaminated natural material such as water.^{246,265} Preparation, use, and maintenance of these solid media and other media are described in other works.^{162,246,265}

Multiple cultures should be obtained from patients with leptospirosis because the concentration of organisms in blood at any point in time is low.¹³² Freshly drawn blood is most desirable, but leptospires may remain viable in anticoagulated blood for as long as 11 days.²⁴⁵ Blood should be inoculated into several tubes of semisolid media. The number of drops of blood placed into each tube should be varied (one to four drops). Excessive amounts of blood inhibit the growth of leptospires; hence a small inoculum yields the best results.⁹⁴ Cultures are incubated at 28°C to 30°C in the dark for 6 weeks or longer.

In semisolid media, leptospires grow in a concentrated ring about 0.5 to 1 cm below the surface. Growth may not be detected in Fletcher semisolid medium for several weeks but may occur earlier in polysorbate medium.

Contaminated specimens or suspensions of primary cultures in which contamination is suspected may be inoculated into hamsters. When an animal dies, phlebotomy or necropsy is performed, and sections of liver, kidney, and brain then are recultured in appropriate semisolid media.

If collected during the septicemic phase, CSF may be cultured in the same manner as blood.

Urine serves as the main source from which leptospires can be isolated during the immune and convalescent phases of leptospirosis. Prolonged urinary shedding after infection is possible in humans. Chow and coworkers reported a 10-year-old girl who shed leptospires in urine for 6 weeks after exposure.⁵⁸ Clean-voided urine may be inoculated directly into an appropriate semisolid medium. Urine specimens must be diluted with sterile, buffered saline solution to ensure growth.²⁵³ Best results are obtained by adding 0.1 mL of urine to 0.9 mL of buffered saline before inoculation into 5 mL of semisolid medium. This procedure can be continued with four additional dilutions. Other bacterial contaminants that may be present in undiluted urine cultures generally do not survive in these cultures after dilution.²⁴⁶

Identification by Means Other Than Culture

The morphologic appearance of all members of the genus *Leptospira* is similar. They are slender, threadlike organisms about 0.1 μ m in diameter and 6 to 12 μ m in length, tightly coiled on their long axis. Like other spirochetes, they cannot be seen in wet preparations by lightfield microscopy, but on darkfield examination they may be observed readily. For the detection of one leptospire per high-power field by darkfield examination, a concentration of 10,000 to 20,000 leptospires per milliliter of fluid is needed.²⁶⁵ At best, darkfield examination should be considered an aid that may suggest but not establish a diagnosis of leptospirosis.

Leptospires can be stained by several silver impregnation techniques.^{44,140,162,246,265} The modified method of Van Orden has been used at the CDC for demonstrating organisms in sections of liver, kidney, or other tissues. Infecting serotypes cannot be differentiated by silver impregnation techniques. Leptospiral antigen also has been detected with the use of an immunoperoxidase staining procedure.⁹¹

Fluorescent antibody techniques may be applied successfully to the detection of leptospires in urine or tissue.^{173,174,246,265} This test is based on specific antigen-antibody reactions using fluorescence-tagged antisera. In theory, the fluorescent antibody reaction should demonstrate distorted and fragmented, as well as whole, organisms, but caution is required. Control specimens that have been treated with unlabeled antiserum before the addition of fluorescein-labeled antiserum should be used.¹⁶² The control specimen should not fluoresce. The fluorescent antibody technique may provide the physician with useful information in the course of the disease in some patients. Positive results, however, are considered only presumptive evidence of infection.

In addition to this technique, DNA hybridization techniques or nucleic acid amplification procedures, including PCR protocols using *Leptospira*-specific cDNA probes or oligonucleotide primers, can be used to detect the presence of leptospires in body fluids or culture supernatants.³⁷ These techniques are being developed in the laboratories

of the Leptospirosis Branch at the CDC, but proof of their superiority in terms of sensitivity or specificity in detecting leptospiral organisms in body fluids or other clinical samples has not been established.

The reference method for serovar identification is considered to be the cross-agglutinin absorption test (CAAT) but requires maintenance of large panels of reference antisera and live antigens. Multilocus sequence typing has been applied to provide strain information but is limited to a few species.¹⁷⁸ Pulse-field gel electrophoresis can be used to identify *Leptospira* to the serovar level, is applicable to all pathogenic species, and can rapidly identify new serovars.⁹⁷

Serologic Tests

Evaluation of serologic findings to supplement clinical and epidemiologic information generally is recommended as a first step in establishing a diagnosis of leptospirosis. One of the most widely used specific serologic tests for leptospirosis has been the MAT, in which live antigen is used. This test is time-consuming and potentially hazardous to the technician but is considered the reference test against which all other tests are evaluated. Formalized antigens can be used for the MAT, and they are preferred in some laboratories, but the titers obtained are lower than those obtained with live antigen, and more cross-reactions with heterologous serotypes occur. Generally, serum is used for the MAT or other agglutination tests, but CSF, urine, bile, or aqueous humor may be used as well.¹⁶²

The CDC uses a standard panel of commonly occurring serovars for routine performance of the MAT. However, because of geographic differences in serovar distribution, serovars are added or changed depending on the region where exposure occurred and the location from which specimens were obtained. Killed antigens remain stable for at least 12 months and are available commercially either individually or in pools. Sulzer and associates²⁴⁶ have provided detailed descriptions of methods for performance of the MAT. Modifications of the MAT have been developed and include the semi-micromethod and microtiter techniques.⁹⁸

A newer serologic test involving diffusion in gel, the enzyme-linked immunosorbent assay (ELISA), has been compared with the MAT for the serologic diagnosis of leptospirosis.^{71,279} The results suggest that this test is a viable alternative to the MAT because of its sensitivity, potential for standardization, and simplicity. Variations of this test have been developed; rapid serodiagnosis of leptospirosis with the use of an IgM-specific dot ELISA has proved to be as sensitive and specific as MAT.^{277,284} The dot ELISA is inexpensive, simple to perform, and uses minute volumes of leptospiral antigens.

The IgM-PK ELISA, an assay for IgM using a proteinase K-treated antigen, was compared with the Leptoteste-S macroagglutination test and with the MAT for the diagnosis of leptospirosis. All three tests were comparable in their ability to detect the presence of leptospirosis. Both the IgM-PK ELISA and the Leptoteste-S differed statistically from the MAT in terms of the positivity of acute phase sera. Thirty-eight percent of patients with leptospirosis were identified earlier with either test than when the MAT was used. The IgM-PK ELISA, which had a sensitivity of 89.9% and a specificity of 97.4%, has been suggested as the test of choice for laboratories that are equipped to perform ELISA.¹⁹⁹

A slide agglutination test available commercially has been compared with the ELISA IgM and has yielded equivalent results for the diagnosis of leptospirosis. The slide agglutination test is inexpensive and can be performed more quickly and more easily than ELISA, thus rendering it a useful test for laboratories that are less well equipped than those in which IgM ELISA currently is performed.⁴²

The Lepto Dipstick, a dipstick assay for detection of *Leptospira*-specific IgM antibodies in serum, has been studied as a method for the diagnosis of leptospirosis in situations in which laboratory facilities may not be available.²³² This test's results correlated well (80–96.7% observed agreement; κ value, 0.62–0.92) with results obtained by the IgM ELISA leptospiral antigen detection method.^{24,113} A 93.2% agreement (κ value, 0.66) was reported between the Lepto Dipstick and MAT, along with a high number of false-positive results as well.²⁴ The dipstick test is a valuable and useful tool for rapid screening for leptospirosis and may be useful in the field for detecting and monitoring outbreaks of leptospirosis. Leptocheck, a simple and rapid commercially available

immunochromatographic test (which can be used on serum or urine) has also been proved helpful in early diagnosis of leptospirosis cases, which should then be confirmed with other serologic methods later.¹⁹²

Other tests that may be used for the serologic diagnosis of leptospirosis include a complement fixation assay, a hemolytic test, an indirect immunofluorescent test, an erythrocyte-sensitizing substance test, countercurrent immunoelectrophoresis, and flow cytometry light scatter analysis.^{56,177,258,295} These tests are genus specific and may yield positive results earlier in the course of leptospirosis than the agglutination tests do. Their results also revert to negative earlier; therefore these tests are of little value for serologic surveys. They may be of value in distinguishing current from past infections when agglutination test results are equivocal.^{245,246}

An indirect hemagglutination test offers the advantage of detecting antibodies as early as the fourth day after the onset of illness. It is genus specific, is less time-consuming, and requires just one antigen in the test system. It has excellent sensitivity and specificity, and some investigators have suggested that it may replace the MAT as the screening test of choice.²⁴⁶ Effler and colleagues,⁸³ however, reported discouraging results when this test was used for the diagnosis of leptospirosis in Hawaii.

Agglutination tests have been considered to be serotype specific. Because of the antigenic complexity of leptospires, however, cross-agglutination reactions occur; serotypes that belong to the same serogroup cross-react at high titers. Early in the course of leptospirosis, heterologous reactions may be stronger than homologous reactions. Because of these paradoxical cross-reactions, one should not depend on serologic determination alone to define the infecting serotype. When agglutination tests are performed on serial specimens over the course of time, the homologous reaction becomes the dominant one in most cases. Performance of agglutination absorption studies may be necessary to define the infecting serotype in some cases. The antigen (serotype) that absorbs out agglutinin to all the serotypes in a serogroup most likely is the infecting serotype.^{162,239,268}

A passive microcapsule agglutination test that uses chemically stable microcapsules instead of sheep erythrocytes has been developed.¹⁷ When compared with the MAT, the passive microcapsule agglutination test showed a relatively greater degree of genus specificity and 4- to 32-fold higher titers. The sensitized microcapsules were stable for at least 1 year. This test is simple to perform and reproducible and can be used readily in the routine laboratory. Moreover, the test appears to be more sensitive than is the MAT in the early stages of leptospirosis.²²¹

A positive leptospiral agglutination reaction generally is not found until the 6th to 12th day of illness, and maximal levels are reached between 21 and 28 days. After recovery, low titers may persist for many years. One blood sample should be obtained early in the course of illness, and a second one should be obtained at the end of 1 month. Negative reactions in serial samples do not exclude the possibility of leptospirosis because patients may be infected with a serotype not included in the battery of test antigens or with a previously unrecognized serotype. Moreover, the titer may have peaked before the acute-phase specimen was collected. Antibiotic therapy also may suppress the development of positive titers or delay their appearance.^{111,162} Peak MAT titers of 1:3000 to 1:100,000 usually are reached during the third week of illness.^{81,268} An unchanging titer of 1:100 on two successive serum specimens has been defined as sufficient for making a presumptive diagnosis of leptospirosis. A fourfold increase in titer between acute and convalescent sera is indisputable evidence of active leptospirosis. The global criterion for laboratory confirmation of a current *Leptospira* infection is usually defined as seroconversion or a fourfold rise in titer in paired serum samples or set at a single MAT titer greater than 1:400 in the presence of clinical signs and appropriate history of animal contact.⁸⁸ Goris and colleagues have recently evaluated the performance of MAT and ELISA in a population in the Netherlands, where positive culture was used as a reference. They also concluded that the sensitivities of MAT and IgM ELISA are low at the acute stage of illness and require a follow-up sample for confirming seroconversion or a significant titer rise, but rather than waiting 2 to 4 weeks for convalescent titers, these could be done much sooner in urgent cases because significant antibody rise was seen in some cases as early as 2 days later, allowing for earlier diagnosis and proper treatment.¹⁰⁷

Leptospira DNA may be detected by PCR at a minimum detection limit of two to three cells per sample.^{150,233} Nonradioactive, arbitrarily

primed PCR assays can be used to discriminate species of *Leptospira*. Romero and colleagues reported that PCR was more likely to facilitate the early diagnosis of leptospiral aseptic meningitis than was either the IgM ELISA or the MAT test.²⁰⁵ Another recent study exploring the use of 16S ribosomal RNA for development of PCR-based diagnostics for human leptospirosis found promising results, perhaps superior to traditional DNA-based PCR.²²

PCR, IgM ELISA, latex agglutination, the Lepto Dipstick assay, and an antibody-based urine antigen assay each may be more sensitive than the MAT early in the course of disease.^{139,184,209}

Unbiased next-generation sequencing aided in diagnosing a case of neuroleptospirosis in a 14-year-old boy with severe combined immunodeficiency who had gone undiagnosed for a period of 4 months with fever and headache worsening to hydrocephalus and seizures. PCR and serologic testing at the CDC subsequently confirmed *L. santarosai* infection, which he had likely contracted on a trip to Puerto Rico.²⁸⁹

TREATMENT

To be of maximum therapeutic benefit, an antimicrobial agent would have to be administered before invading organisms damage the endothelium of blood vessels and various organs or tissues. One of the problems in evaluating the efficacy of treatment is the fact that, generally, leptospirosis is a self-limited disease with a favorable prognosis. Even patients with severe icteric leptospirosis may recover without specific treatment.

Most claims of the beneficial value of antimicrobial agents in human leptospirosis are based on the response of individual patients rather than on controlled studies. Hall and associates¹¹⁶ compared the effects of penicillin, chloramphenicol, chlortetracycline, and oxytetracycline with placebo in 67 confirmed cases of leptospirosis. No appreciable effect of antibiotics could be demonstrated on the duration or severity of illness or on the prevention or amelioration of central nervous system, hepatic, renal, or hemorrhagic complications of this disease. Moreover, the duration of leptospiremia and the persistence of organisms in CSF were not altered by treatment. Kocen¹⁴¹ compared the effects of penicillin administered on the fourth day of illness to 28 patients with a control group of 33 who were given only supportive care and reported that the duration of fever was shorter and the incidence of jaundice, meningismus, renal involvement, and hemorrhagic manifestations was diminished in the treated group.¹⁴¹ None of these controlled studies was entirely satisfactory with respect to randomization of patients.

McClain and associates¹⁵⁷ studied the therapeutic efficacy of doxycycline in military recruits who contracted leptospirosis while training at the Jungle Operations Training Center in Panama. Twenty-nine patients with anicteric disease were treated in a randomized, double-blinded fashion with doxycycline 100 mg orally twice a day or with placebo. Therapy was administered for 7 days in the hospital, after which patients were monitored for 3 weeks. The duration of illness before therapy and the severity of illness were similar in both study groups. Doxycycline shortened the duration of illness by 2 days and favorably influenced fever, malaise, headache, and myalgia. Treatment also prevented leptospiruria, and no significant adverse effects of doxycycline administration were observed.

In another randomized, double-blinded, placebo-controlled field trial at the same military training site, Takafuji and associates²⁵¹ demonstrated that doxycycline in a 200-mg oral dose given weekly or at the completion of jungle training was highly effective in preventing the onset of clinical leptospirosis. Twenty cases of disease were documented in the placebo group (attack rate, 4.2%) as opposed to only one case in the treatment group (attack rate, 0.2%), findings supporting the prophylactic utility of doxycycline in this setting.

Watt and associates²⁸⁵ reported the results of a trial in which a 7-day course of intravenous penicillin with 6 million units per day was compared with placebo in a randomized, double-blinded trial involving 42 patients. All the patients had severe, advanced disease. Every measurable aspect of the disease was affected favorably by penicillin. The duration of fever was shortened significantly ($P < .005$) in the group receiving penicillin. Penicillin therapy decreased the number of days of hospitalization and prevented the development of leptospiruria. These

investigators concluded that intravenous penicillin should be given to patients with severe leptospirosis, even if therapy can be initiated only late in the course of their disease. Subsequently, Costa and associates⁶⁸ reported the contrary. Two hundred fifty-three patients with leptospirosis and longer than 4 days of symptoms were randomized to receive 6 million units of penicillin for 7 days or placebo (mean pretreatment duration of symptoms of 6.6 days and 6.5 days, respectively). Neither the number of days of hospitalization nor the in-hospital case-fatality rate differed significantly between the two groups.

Limited data exist comparing the use of alternative antimicrobial agents with penicillin. Panaphut and colleagues¹⁸⁷ reported no difference in time to resolution of fever, mortality, or duration of organ dysfunction between patients randomized to receive a 7-day course of penicillin or intravenous ceftriaxone. A subsequent study²⁴⁷ comparing penicillin, doxycycline, and cefotaxime reported no significant differences among the three groups with regard to mortality, time to defervescence, or time to resolution of abnormal laboratory test results.

Empiric treatment with penicillin or a tetracycline (to be avoided in children younger than 9 years) early in the course of disease can be used if a diagnosis of leptospirosis is suspected. Parenteral aqueous penicillin G 6 to 8 million units/m² per day in six divided doses should provide optimal blood and tissue concentrations of penicillin. For patients sensitive to penicillin, tetracycline 25 to 50 mg/kg per day orally in four divided doses (up to 3 g/day) or doxycycline 5 mg/kg per day orally in two divided doses (up to 200 mg/day) for 1 week, should be provided.

Management of leptospirosis requires careful attention to supportive care. Fluid and electrolyte balance requires meticulous attention. Dehydration, cardiovascular collapse, and acute renal failure may necessitate prompt and specific treatment. In some cases, acute renal failure may be prevented by ensuring adequate renal perfusion and appropriate fluid administration early in the course of disease, when prerenal azotemia and shock may be seen.^{28,227} If prerenal azotemia is suspected, diuresis should be attempted promptly with administration of a fluid or colloid load designed to expand extracellular volume and replace extracellular fluid deficits.²⁸ In patients who do not respond to such therapy, acute tubular necrosis may be suspected, and appropriate fluid restriction should be initiated. If azotemia is severe or prolonged, peritoneal dialysis or hemodialysis should be instituted.^{13,89,270} The use of exchange transfusion has been suggested in patients with marked hyperbilirubinemia and acute renal failure and may be associated with lower mortality.^{174,183,195,228}

The use of corticosteroids in the treatment of severe cases has not been evaluated critically, but their use in patients with impending hepatic coma has been suggested.⁸² Anecdotal reports also suggest that corticosteroids may be of value in patients with profound hypotension or shock.

PREVENTION

Prevention of leptospirosis, as with many other infections, invokes hygienic practices, immunizations, and prophylaxis after potential exposures. Benches in rat-infested, fish-gutting sheds and sewers may be decontaminated. Hygienic conditions should be encouraged in slaughterhouses, farmyard buildings, and bathing pools. Public health prevention campaigns in Australia emphasize the “cover-wash-clean up” strategy for reducing the incidence of leptospirosis. “Cover” exposed skin and mucous membranes that might come in contact with animals or animal secretions, “wash” hands or shower after a potential contamination, and “clean up” areas that might be contaminated or might attract rodents.²³⁰ Given the rise of leptospirosis acquired during recreation or international travel, travelers should be advised about preventive measures such as avoiding flood waters, wearing protective clothing and boots, and covering up cuts and abrasions on their skin when engaging in outdoor activities.¹⁴⁵ Monitoring water for infection, whether for consumption or recreation, could help prevent exposure. Zhou and colleagues describe a PCR-based DNA microarray system for waterborne pathogen detection in water samples, including *L. interrogans*.²⁹⁶ Identifying contaminated water sources can aid in the prevention of further spread.

In addition to hygiene, prevention of leptospirosis primarily depends on immunization of animals. Human immunization has generally been

restricted to individuals with high-risk occupations and in response to epidemics or following natural disasters. Immunization of workers at high risk for acquiring leptospirosis has been used successfully in those working in mines in Japan and Poland, in rice fields in Italy and Spain, and in sewers in Paris.^{115,267} Leptospire bacterins are available commercially and have been evaluated for safety and efficacy in laboratory animals and domestic livestock.^{40,133,213,237} The degree of protection attained depends largely on the antigenic potential of the immunizing agent. Requirements for the *L. pomona* vaccine used in cattle are such that not more than $1/800$ of the dose recommended for cattle must protect 80% of hamsters challenged intraperitoneally 14 to 18 days after vaccination with a dose of 100 hamster LD₅₀. In contrast, most dogs are immunized with a vaccine that is but $1/10$ of the potency of that used for cattle. Most dogs thus immunized have been protected against disease but not necessarily from carrying and excreting leptospires in their urine. Trends documenting that many cases of leptospirosis in children have been associated with contact with dogs suggest that more stringent requirements for the immunization of pet dogs are needed. The challenge in vaccine efforts has been production of a safe and efficacious vaccine that promotes cross-protection against various pathogenic serovars that will eliminate infection and prevent chronic renal carriage.²⁹⁷ Much of leptospirosis research efforts continue to focus on identification of potential vaccine candidates.⁶ The availability of the genome sequence of *Leptospira* has facilitated this search and provided grounds for continued attempts at finding the ideal vaccine.^{119,169} A detailed review of the literature on vaccines against leptospirosis was recently published. Adler⁶ concludes that despite extensive research and increased knowledge of leptospirosis, the only vaccine licensed for use in animals and humans are inactivated bacterins not very different from those first used 90 years ago. There have been and continue to be active attempts at identifying leptospiral proteins that are able to elicit cross-protective immunity, but true success has yet to be reached. Promising candidates under judicious study include LipL32 and LigA.⁶ The search for the perfect vaccine continues.^{128,269,278}

A randomized trial of doxycycline versus placebo was undertaken to assess the efficacy of doxycycline prophylaxis in the prevention of infection and disease caused by leptospires during outbreaks in North Andaman.²¹⁹ Leptospiral infection was not prevented, but the patients who received doxycycline and in whom disease subsequently developed had lower morbidity and mortality rates.

Spirillum minus is one of the two known causative agents of rat-bite fever. Rat-bite fever also may be caused by *Streptobacillus moniliformis* (see Chapter 138). *S. minus* is a spirochete that was first isolated in 1917 and was reported to be a common cause of rat-bite fever in Asia, although few reports exist in the English literature to confirm its prevalence.^{5,9} Few cases of spirillary rat-bite fever have been reported in the American literature in the past 4 decades, with most cases reported in the early 1900s.^{3,5,13} No confirmed cases have been reported in the last 25 years. Many reports discuss both etiologies simultaneously, although the two types of rat-bite fever are distinct with different epidemiology and clinical presentations.

BACTERIOLOGY

S. minus is a short, rigid, aerobic, gram-negative, flagellated spirochete measuring 2 to 5 μm in length. The organism is thicker and more rigid than *Treponema pallidum* and usually contains two to three regular sharp turns along its length. On darkfield microscopy, the organism moves quickly with the use of a terminal flagellum.⁵ *S. minus*, like other spirochetes, does not grow on artificial media and requires animal inoculation for successful isolation.¹⁵ However, two reports in the literature describe the isolation of *S. minus* in broth,^{8,14} but these cases may have represented other infectious illnesses.

EPIDEMIOLOGY AND PATHOLOGY

Like streptobacillary infection, disease appears to be transmitted primarily through rat bites. In 1928 approximately 25% of rats were carriers of *S. minus* in the nasopharynx, and rats with conjunctivitis were shown to have *S. minus* in the eye discharge that drained into their mouths.¹¹ Disease has not been reported after oral ingestion of the organism. Human-to-human transmission has not been reported but conceivably could occur during blood transfusions.

Gunning⁶ gave an excellent description of the pathologic changes associated with *S. minus* infection. The infection provokes edema, mononuclear leukocyte infiltration, and necrosis at the site of inoculation. Regional lymph nodes are hyperplastic. The relapsing symptoms are associated with invasion of the blood by spirilla. Toxic, hemorrhagic, or necrotic changes may occur in the liver and kidney.

CLINICAL MANIFESTATIONS

The original description by Futaki and colleagues⁵ described “the clinical symptoms of rat-bite fever are inflammation of the bitten parts, paroxysms of fever of the relapsing type, swelling of the lymph glands, and eruption of the skin, all occurring after an incubation period usually from 10 to 22 days, or longer.” The incubation period of spirillary rat-bite fever typically is longer than that of the streptobacillary form, with an average of 14 to 18 days and a range of 1 to 36 days.² The disease is heralded by the appearance of an indurated lesion at the site of the initially healed bite, which coincides with the onset of fever and chills. Chancre formation or ulceration may occur at the site, and regional lymphadenopathy is a common finding. The temperature may reach

41°C (105.8°F) in a stepwise fashion over the course of 2 to 4 days and then fall abruptly.⁶

Six to eight regularly occurring relapses of fever may occur, separated by afebrile periods lasting 3 to 7 days. During febrile periods, the patient also may experience myalgia, headache, and vomiting. In approximately 50% of patients, a purple to red-brown rash develops and consists of large macules with occasional indurated erythematous plaques or urticarial lesions.¹⁵ In contrast to streptobacillary rat-bite fever, joint manifestations are rare occurrences. In untreated cases, the illness may persist for 3 to 8 weeks, but relapses have occurred after months or years.¹³

Spontaneous cure is the general rule, but several untreated cases persisted for more than 1 year.¹⁵ The untreated mortality rate was reported to be 6.5% in 1942.² In protracted, untreated cases, severe complications included endocarditis,⁸ meningitis,¹⁰ myocarditis, hepatitis, and nephritis.⁴ Anemia, weight loss, and severe diarrhea were common complications in infants and children. Epididymitis, nuchal rigidity, headache, pleurisy, pleural effusion, and splenomegaly also were reported.¹² Mortality was noted to be significantly lower than in streptobacillary rat-bite fever.¹³ Herxheimer reactions were reported in patients treated with arsenic-based therapies used before penicillin.¹³

The differential diagnosis includes streptobacillary rat-bite fever as well as many other infectious and noninfectious diseases (see Chapter 138).

DIAGNOSIS

Definitive diagnosis requires isolation and identification of the spirochete. The organism rarely may be seen on a peripheral blood smear with Giemsa or Wright stain^{1,3} or darkfield examination of ulcer exudate.⁷ Animal inoculation usually is required for isolation. Blood or wound aspirates are injected intraperitoneally into guinea pigs or mice. The spirochetes then may be recovered in 5 to 15 days from the animals' blood, which is examined under darkfield microscopy. This process is time consuming and may not be available in most centers. In addition, the inoculated animals must be screened carefully for previous *Spirillum* carriage.

Nonspecific diagnostic criteria include a false-positive test for syphilis in 50% of patients, white blood cell count between 10,000 and 20,000 cells/mm³,⁵ and moderate anemia.^{2,15} No specific serologic tests are available for *S. minus*. Molecular methods, such as polymerase chain reaction, may offer hope in the future for detection of *S. minus*.⁴

TREATMENT

Before penicillin, *S. minus* was treated successfully with arsenic therapy; however, response was slower, with reported relapses and even death.¹³ In general, *S. minus* is considered more sensitive to penicillin than *S. moniliformis*, and penicillin is the drug of choice for both forms of the disease. Doses as low as 24,000 U/day for 5 days were shown to be effective.¹³ However, because distinguishing spirillary disease from streptobacillary disease may be difficult, it is important to treat initially with higher dosages effective against *S. moniliformis* (see Chapter 138).

Syphilis was recognized first at the end of the 15th century in Europe, where it appeared seemingly as an emerging infectious disease. It rapidly spread to reach epidemic proportions. Its European origins are a mystery that will not be solved easily, with theories ranging from its being a disease introduced from the New World by the returning crew of Columbus to its being a virulent form of the endemic yaws and bejel of African peoples that appeared later as virulent syphilis in a susceptible European population.

Syphilis initially was called the *Italian disease*, the *French disease*, and the *great pox* (as distinguished from smallpox). Its venereal transmission was not recognized until the 18th century. Delineation of characteristics of syphilis was hindered by the confusion of its symptoms with those of gonorrhea. In 1767, Hunter, a great English experimental biologist and physician, inoculated himself with urethral exudate from a patient with gonorrhea. The patient also had syphilis, and the subsequent symptoms experienced by Hunter convinced two generations of physicians of the unity of gonorrhea and syphilis. The separate natures of gonorrhea and syphilis were shown in 1838 by Ricord, who reported his observations on more than 2500 human inoculations. Recognition of the stages of syphilis followed; in 1905, Schaudinn and Hoffman discovered the causative agent. The following year, Wassermann introduced the diagnostic blood test that bears his name.

ORGANISM

Morphologic characteristics are the primary features by which members of the family Spirochaetaceae are placed into a single taxon. Spirochetes are helix-shaped, heterotrophic bacteria. These organisms are slender, coiled, and flexible, with one or more complete turns in the helix. Spirochetes are motile, their corkscrew motility resulting from the action of axial fibrils known as *endoflagella*. The family Spirochaetaceae has five genera, of which only *Treponema*, *Borrelia*, and *Leptospira* spp. cause major human illnesses. Differentiation among genera of the family Spirochaetaceae is based primarily on the morphology of the organism.

The name *Treponema* is derived from the Greek words meaning “turning thread.” Individual organisms are 5 to 15 μm in length and 0.092 to 0.5 μm in diameter and have finely tapered ends. Whole cells appear to have a flat wave with one or more planes per cell, giving the appearance of a helical coil. Each cell has 8 to 14 evenly distributed waves. They exhibit a sluggish mobility, with drifting motion and graceful flexuous movements.⁷³ The internal structure of *Treponema pallidum* subsp. *pallidum* generally is similar to that of other spirochetes. An outermost thin three-layered membrane surrounds the protoplasmic cylinder of the cell. Intracytoplasmic microtubules have been described, and such structures may be specific for *Treponema* spp.

The six axial fibrils or endoflagella are long, flagella-like, intracellular organelles that originate at either end of the cell from knoblike structures and extend toward the other end. Axial fibrils vary in length but overlap one another near the middle of the cell. These fibrils are thought to determine the spiral shape of the cells and are responsible for the characteristic motility along the longitudinal axis exhibited by members of Spirochaetaceae.

The complete genome of *T. pallidum* subsp. *pallidum* (Nichols strain) was sequenced by the whole-genome rapid sequencing method.⁴⁷ The *T. pallidum* genome is a circular chromosome and is small compared with most bacteria at 1.14 Mb that encode 1041 predicted proteins. By polyacrylamide gel electrophoresis technique, the major constituent proteins of *T. pallidum* have been characterized and include integral membrane proteins with apparent molecular masses of 47, 34, 17, and 15 kDa.¹⁰² These lipoprotein antigens are highly immunogenic in laboratory animals and humans.^{7,65}

Virulent strains of *T. pallidum* are propagated by intratesticular inoculation of rabbits, and the inability to propagate the organisms in vitro has hampered study of these microorganisms. The time required for division of the organism to occur in rabbits is slow, at approximately 30 hours. Velocity sedimentation employing discontinuous gradients of radiocontrast medium (Hypaque) successfully has purified and concentrated treponemes extracted from infected rabbit testes. These organisms retain the antigens for the fluorescence test, although motility is lost.

Limited cultivation of *T. pallidum* on monolayers of baby hamster kidney cells in 7% carbon dioxide has been reported. Research with in vitro characteristics of these organisms also has resulted in the description of adherence of virulent *T. pallidum* to primary cell cultures of rabbit testicular cells and to an established continuous line of human epithelial cells (HEp-2). To date, however, direct in vitro culture for establishing the diagnosis of *T. pallidum* disease has not been possible. In vitro growth is hindered by the reliance of *T. pallidum* on glycolysis alone for adenosine triphosphate synthesis, its sensitivity to oxygen, and its sensitivity to growth temperature.⁷³

Other pathogenic *Treponema* organisms cause characteristic clinical diseases and now are known to be genetically different from *T. pallidum* subsp. *pallidum*. These are *T. pallidum* subsp. *carateum* (pinta), *T. pallidum* subsp. *endemicum* (bejel or endemic syphilis), and *T. pallidum* subsp. *pertenue* (yaws). Several nonpathogenic treponemes also inhabit the oral cavity and intestinal tract.¹⁹

TRANSMISSION

Acquired Syphilis

Syphilis is not a highly contagious disease. An individual who has had sexual contact with an infected partner has approximately a 30% chance of acquiring disease. The median infective dose to humans experimentally has been estimated to be 57 organisms. *T. pallidum* has the capability to invade the intact mucous membrane or microabrasions of the skin. Direct inoculation from contact with an infected individual is necessary for infection to occur because survival of the organism outside the host is very limited. The organism is killed easily by heat, drying, soap, and water. Sexual contact is the common method of transmission of acquired disease, and the site of inoculation usually is on the genital organs—the vagina or cervix in females and the penis in males. Other sites include lips, breast, tongue, and abraded areas of the skin. Examining physicians and pathologists may be infected by contact if appropriate barrier protection is not used.

Congenital Syphilis

Congenital syphilis usually results from transplacental infection of the developing fetus from spirochetes in the maternal bloodstream. *T. pallidum* becomes widely disseminated to many tissues in an adult soon after initial infection occurs even if clinical manifestations are delayed by months. Maternal spirochetemia and placental infection are not surprising findings.⁹ A neonate occasionally may be infected at delivery by contact with an infectious lesion present in the birth canal or perineum. Intrauterine transmission is supported by isolation of the organism from umbilical cord blood and amniotic fluid,^{52,99,127,149} detection of spirochetes in the placenta and umbilical cord in association with typical histopathologic changes,^{41,46,112} and detection of specific immunoglobulin M (IgM) antibody to *T. pallidum* in neonatal serum obtained at birth.^{82,91,124,127} The isolation of *T. pallidum* from 74% of amniotic fluid specimens obtained from women with early syphilis also suggests that the organism is capable of traversing the fetal membranes, gaining access to the amniotic fluid and resulting in fetal infection.⁸³ Breastfeeding is not associated with transmission of syphilis, unless the mother has a chancre on her breast.

Transmission of syphilis to the fetus can occur throughout pregnancy. Occasional reports in the literature describing treponemes in fetal tissue or placentas before the fifth month of gestation were disputed for decades.⁴⁰ The thought was that the Langhans cell layer of the cytotrophoblast formed a placental barrier against treponemal invasion of the fetus. Researchers subsequently showed, however, that the layer of Langhans cells in the placenta persisted throughout pregnancy.

In 1976, Harter and Benirschke⁵⁷ visualized spirochetes by Warthin-Starry silver stain and immunofluorescence in tissue from two aborted fetuses at gestational ages of 9 and 10 weeks. The expected inflammatory response was not observed in these two fetuses, but such changes have been found in infected fetuses after the 15th week of pregnancy. These investigators noted that researchers describing syphilitic fetuses or placentas in the older literature worked with the products of spontaneous abortions. Such fetal loss caused by syphilis occurred only after 18 weeks of gestation, implying that the fetal loss was a reflection of damage incurred as a result of the host response to the organism. The observation of sequential acquisition by the fetus of the ability to respond to a variety of antigens suggests that inflammation can be present only after the fetus acquires the immunologic ability to recognize the treponeme.¹³⁶ The detection of spirochetes in amniotic fluid obtained by amniocentesis from a woman with early syphilis at 14 weeks of pregnancy has shown that the fetus can be infected with *T. pallidum* in early pregnancy.⁹⁸ The rate of vertical transmission does increase with advancing gestation, however.

Vertical transmission is related directly to the maternal stage of syphilis, with early syphilis resulting in significantly higher transmission rates than late latent infection. Generally, the greater the time that has elapsed since the woman's primary or secondary infection, the less likely she is to transmit disease to the fetus. Ingraham⁶² reported in 1950 that among 251 women with syphilis having a duration of 4 years or less, 41% of their infants were born alive and had congenital syphilis; 25% were stillborn; 14% died in the neonatal period; 21% had low birth weight, but no evidence of syphilis; and 18% were normal full-term infants. In contrast, only 2% of infants born to mothers with late disease had congenital syphilis. In 1952, Fiumara and colleagues⁴⁴ reported that untreated primary or secondary syphilis resulted in 50% of infants having congenital syphilis, whereas the other half were stillborn or premature or died in the neonatal period. With early latent infection, 40% of the infants had congenital syphilis, whereas only 10% with late latent disease developed syphilis. These data are supported by a more recent study of Sheffield and colleagues,¹³² in which mothers with primary, secondary, early latent, and late latent infection had transmission rates of 29%, 59%, 50%, and 13%, respectively.

Syphilis is an ulcer-causing disease that is associated with increased sexual transmission of human immunodeficiency virus (HIV). In this regard, increasing numbers of neonates who are infected with congenital syphilis also are born to mothers with HIV, and vice versa. The contribution of maternal coinfection with *T. pallidum* and HIV to vertical transmission of either syphilis or HIV has not been elucidated fully. Virulent *T. pallidum* can promote the induction of HIV gene expression in macrophages, possibly resulting in increased systemic HIV levels and more rapid progression of the HIV infection.¹⁴⁴ A more recent study noted higher rates of congenital syphilis in infants born to coinfecting mothers, but the diagnosis of congenital syphilis was based on a surveillance definition used by the Centers for Disease Control and Prevention (CDC) and not on strict diagnostic criteria.¹²⁹

EPIDEMIOLOGY

The introduction of penicillin in 1942, and its subsequent widespread use in the 1950s, resulted in a marked decline in the occurrence of syphilis in the United States. After an increase in the number of cases occurred in the early 1960s, the rates again declined in the 1970s, only to have a dramatic resurgence from 1986 to 1991.^{21,30,117} The rapid increase during these years in the rate and numbers of cases of primary and secondary syphilis in adults, specifically among women of childbearing age, resulted in a significant increase in rates of congenital syphilis. Rates of syphilis were greatest among blacks and Hispanics residing in large urban centers. The disease was centered in populations in which substance abuse, particularly crack cocaine, was common and where there was involvement with the sex trade industry often in exchange for drugs.²¹

Other factors that may have contributed to the increased rates of syphilis included underfunded and overwhelmed public health resources; use of spectinomycin for treatment of penicillinase-producing *Neisseria gonorrhoeae* because spectinomycin is ineffective against incubating syphilis; and failure to implement safer sexual practices, especially among adolescents and young adults. Generally, individuals who acquire syphilis characteristically are young and often have had contact with an average of five individuals during the incubation period. Because of the high rate of dual infection (8%) with *N. gonorrhoeae*, some individuals identified and treated for gonorrhea with ceftriaxone also are treated for syphilis while in the preprimary stage of disease.

Strenuous attempts were made to control syphilis, and the lowest rate ever reported in the United States was reached in 2000, with the rate of primary and secondary syphilis declining by 90% between 1990 and 2000 to 2.1 per 100,000 population.²³ The reasons for this decline included (1) wider screening practices secondary to medical and public awareness of the syphilis epidemic of the late 1980s that led to identification and treatment of infected individuals; (2) increased state and local funding for syphilis control programs such as partner notification, community-based screening and presumptive treatment strategies, and risk-reduction counseling; (3) introduction of HIV prevention programs that target prevention of other sexually transmitted infections (STIs); (4) decrease in crack cocaine use and trading sex for drugs behaviors; and possibly (5) development of acquired immunity to syphilis among high-risk populations that resulted in less reacquisition of infectious syphilis.

The concentration of cases in the United States to a few geographic areas, especially in the southeastern United States, led to an optimistic "National Plan to Eliminate Syphilis" announced by the CDC in 1999.¹⁴⁰ The plan had to be restated in 2006 in the presence of resurgent rates.²³ A gender gap has been noted, with rates of primary and secondary syphilis in men increasing from 3 per 100,000 in 2001 to 5.7 per 100,000 in 2006. The increase in male rates has been explained partly by cases in men who have sex with men and attributed to high-risk sexual behaviors and coinfection with HIV. In 2006, there also was an increase in rates in women from 0.8 per 100,000 in 2004 to 1 per 100,000. With the rates increasing in heterosexuals, the rates of congenital syphilis also have rebounded.

In 1987, the reported rate of congenital syphilis was 10.5 cases per 100,000 live births. By 1991, there were 4398 cases of congenital syphilis (107 per 100,000 live births). These rates reflect a reporting surveillance case definition that was changed in 1988^{21,156} and resulted in an almost fourfold increase in the number of cases reported to the CDC.³⁰ There also was a genuine increase, however, in the number of actual cases and case rates secondary to the increase in early syphilis among women.⁷⁰ Canadian rates had followed a similar trend where it was notable that delayed access to antenatal care was a key factor, in that all women who were delivered of infants with congenital syphilis had histories of substance abuse and street involvement.¹³⁷

In 1988, investigators recognized that prior definitions of congenital syphilis that had been used for surveillance and for treatment decisions had been difficult to apply to the clinical setting because they required a diagnosis that often could be established only over weeks or months. During that period, many children were lost to follow-up and were neither treated nor reported.³⁰ Because of the high incidence of congenital disease in infants born to inadequately treated mothers, current definitions of congenital syphilis for a presumptive case (which should be reported and treated) require only (1) that the infant be born to a mother with untreated or inadequately treated syphilis or (2) that the child have physical or laboratory signs of congenital syphilis. A summary of the surveillance case definition used since 1988 is provided in [Box 144.1](#).

Minor differences exist among case definitions of congenital syphilis as formulated by several agencies and experts.¹²² Some experts would consider as a presumptive case a neonate who is well clinically but was born to a mother who had contact within 90 days before delivery with an individual with primary or secondary syphilis and who had not been treated or had been treated inadequately, even if the mother has nonreactive serology. Although recommendations for therapy commonly have assumed that adequate therapy given to a mother with primary or secondary syphilis during pregnancy would prevent congenital syphilis with a high degree of reliability, reasons to doubt this premise have emerged.^{3,88,155} In particular, treatment failures in which the infant

BOX 144.1 Surveillance Case Definition for Congenital Syphilis

A confirmed case of congenital syphilis is when *Treponema pallidum* is identified by darkfield microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, umbilical cord, amniotic fluid, or autopsy material.

A presumptive case of congenital syphilis can occur in either of the following:

- A. Any infant whose mother had untreated or inadequately treated^a syphilis at delivery, regardless of findings in the infant, or
- B. Any infant or child who has a reactive treponemal test for syphilis and any one of the following:
 - 1. Any evidence of congenital syphilis on physical examination, or
 - 2. Any evidence of congenital syphilis on long bone radiograph, or
 - 3. Reactive cerebrospinal fluid VDRL, or
 - 4. Elevated cerebrospinal fluid cell count or protein (without other cause), or
 - 5. Quantitative nontreponemal serologic titers that are fourfold higher than the mother's (both drawn at birth), or
 - 6. Reactive test for FTA-ABS-19S-IgM antibody

A syphilitic stillbirth is defined as a death of a fetus weighing >500 g or having a gestational age >20 weeks in which the mother had untreated or inadequately treated syphilis at delivery.

^aInadequate treatment consists of any nonpenicillin therapy or penicillin given <30 days before delivery.

BOX 144.2 Circumstances in Which Maternal Therapy for Syphilis May Be Subtherapeutic or Inadequate

- Treatment with a nonpenicillin regimen (including macrolide antibiotics)
- History of maternal treatment was not documented fully or verifiable
- Treatment during the month before delivery
- Treatment in HIV-infected women
- Serial posttherapy assays of maternal nontreponemal antibody titers were not performed
- Serial posttherapy assays of maternal nontreponemal antibody titers did not show a fourfold decline in titers after treatment of early syphilis, not permitting assessment of adequacy of therapy, and suggesting possibility of failure to eradicate infection
- Serial posttherapy assays of maternal nontreponemal antibody titers show a fourfold increase in titers, suggesting reinfection or relapse

developed syphilis despite maternal therapy have been reported when the mother was treated first within 30 days of delivery.^{10,14,87,101,121}

An infant born to a mother who was treated within 30 days of delivery is considered to have been treated inadequately, and the infant should receive appropriate therapy. Box 144.2 lists the various circumstances in which maternal therapy may be presumed to be subtherapeutic. The consequences of inadequate therapy for the mother are shown in data in Table 144.1. In that experience, 13% of children born to inadequately treated mothers had congenital syphilis, all of which was neurosyphilis.¹²⁰

Substantial underreporting of infected infants did occur previously,³⁷ but the revised surveillance definition does not represent diagnostic criteria. Rather, it reflects the public health burden of the disease because these infants require medical and public health interventions. Notwithstanding this change in reporting guidelines, the number of cases of congenital syphilis had continued to decline from a peak of 107 per 100,000 live births in 1991. In the United States, the rate of congenital syphilis decreased during 1991–2005 but increased slightly during

TABLE 144.1 Clinical Findings of 148 Infants Whose Mothers Had Syphilis

Infant Findings	MATERNAL TREATMENT

2005–08. The overall rate of reported congenital syphilis decreased from 10.5 to 8.4 cases per 100,000 live births during 2008–12, and then increased to 11.6 cases per 100,000 live births in 2014, the highest congenital syphilis rate reported since 2001. From 2012–14, reported cases and rates of congenital syphilis increased across all regions of the United States, reflecting a parallel 22% national increase in the rate of primary and secondary syphilis among women during the same period. Lack of prenatal care remained the most important factor.¹²

Worldwide, syphilis remains a considerable public health problem. Mother-to-child transmission cannot be easily measured globally because definitive diagnosis is difficult. Estimating the burden of disease must rely on modeled data. In 2007 the World Health Organization (WHO) reported global estimates for congenital syphilis burden based on a review of published data from 1997 through 2003. They estimated that annually there were 2,036,753 syphilis infections among pregnant women, of which 65% (1,323,889; range, 728,547–1,527,565) resulted in adverse pregnancy outcomes, including early fetal loss, stillbirths, and neonatal deaths.¹²⁸ In 2007, WHO launched an initiative to eliminate congenital syphilis that set targets of at least 90% of pregnant women being tested for syphilis and at least 90% of seropositive pregnant women receiving adequate treatment by 2015.¹⁵² To facilitate assessment of the initiative's progress, a more up-to-date model was developed using global and regional health services delivery data to estimate the burden of syphilis in pregnancy in 2008. An active syphilis infection occurred in 1.4 million pregnant women, 80% of whom had attended antenatal care services. Infection caused 520,000 adverse outcomes in 2008, including 215,000 stillbirths or fetal deaths, 90,000 neonatal deaths, 65,000 preterm or low-birth-weight infants, and 150,000 infants with congenital disease. Almost two-thirds of the adverse effects occurred in women who had attended antenatal care but were either not tested or not treated for syphilis. For those tested at antenatal clinics, regional seropositivity rates among antenatal care attendees were Africa 2.13%, Asia 0.62%, Europe 0.16%, and the Americas 0.84% (Fig. 144.1).¹⁰⁰

Congenital syphilis is a disease that should be amenable almost fully to eradication if currently available prenatal health measures were implemented completely. Table 144.2 presents two studies in the United States of prenatal care of women who were delivered of infants with congenital syphilis and indicates the hurdles that control of the disease will have to overcome.^{31,88} Lack of optimal prenatal care is the most important one.^{35,90,147} National surveillance data analyzed by the CDC in 2002 highlight the fact that cases of congenital syphilis still occur even when prenatal care is implemented if the mother's response to treatment is inadequate or if the infant's evaluation is not thorough (Fig. 144.2).²²

Globally, the WHO initiative has been acted on with emphasis on (1) ensuring advocacy and sustained political commitment, (2) increasing access to maternal and newborn services, (3) screening and treating pregnant women and their partners, and (4) establishing surveillance, monitoring, and evaluation systems. The last is especially important in terms of allowing for a process to validate countries as being free of mother-to-child transmission of syphilis.^{66,153} Several countries have now achieved this status, including Cuba (2015) and Thailand, Moldova, Armenia, and Belarus (2016).

PATHOLOGY

Syphilis often is a lifelong infection that progresses in three clear characteristic stages (Fig. 144.3). After initial invasion occurs through mucous membranes or skin, the organism undergoes rapid multiplication and is disseminated widely. Spread through the perivascular lymphatics and then through the systemic circulation probably occurs even before the clinical development of the primary lesion. Ten to 90 days later, usually within 3 to 4 weeks, the patient manifests an inflammatory response to the infection at the site of the inoculation. The resulting lesion, the chancre, is characterized by the profuse discharge of spirochetes; accumulation of mononuclear leukocytes, lymphocytes, and plasma cells; and swelling of capillary endothelia. The regional lymph nodes are enlarged, and the cellular infiltrate resembles that of the primary lesions. Resolution of the primary lesion occurs by fibrosis.

Secondary lesions develop when tissues of ectodermal origin, such as skin, mucous membranes, and central nervous system (CNS), participate in an inflammatory response. Mucous patches in the mouth are caused by local vasculitis. The cellular infiltrate resembles that of the primary lesion,

with the predominance of plasma cells. Little or no necrosis is present, and healing is without scarring but may include pigmentary changes.

Tertiary syphilis may involve any organ system and often is asymmetric. Gummas are lesions typified by extensive necrosis, a few giant cells, and a paucity of organisms. They commonly occur in internal organs, bone, and skin. The other major form of tertiary lesion is a diffuse chronic inflammation, with plasma cells and lymphocytes but without caseation, which may result in an aneurysm of the aorta, paralytic dementia, or tabes dorsalis. Chronic swelling of the capillary endothelium and fibrosis result in the characteristic tissue changes.

Congenital syphilis is a result of hematogenous infection and the disseminated involvement of almost all viscera. The intense inflammatory response occurs in the perivascular framework and interstitial stroma, rather than in the parenchyma.⁹⁷ Bone, liver, pancreas, intestine, kidney, and spleen are involved most reproducibly and severely. Other tissues, such as the brain, pituitary gland,¹⁴ lymph nodes, and lungs, also may be infected. The gastrointestinal tract shows a pattern of mononuclear cell infiltration in the mucosa and submucosa, with subsequent widening of the submucosa by the ensuing fibrosis. This event is most prominent

in the small bowel. In the kidney, a perivascular inflammation, particularly in the juxtamedullary region, is evident. The basic architecture of the tissue influences the ultimate pattern of involvement. The deposition of collagen around arteries of the spleen produces a typical onionskin appearance. Periosteum and epiphyses are the most affected portions of bone, and syphilitic granulation tissue may interfere with bone formation. Pancreatitis also is observed, with typical inflammation and fibrosis.

The fetus or neonate shows diffuse extramedullary hematopoiesis in many tissues. The placenta of infants with congenital syphilis often

is large, thick, and pale. Three histopathologic features commonly are seen: enlarged and hypercellular villi, proliferative fetal vascular changes, and acute and chronic inflammation of the villi.^{50,132} Erythroblastosis involving the placenta has been seen more frequently among stillborn infants with congenital syphilis than in live-born infants with or without syphilis.¹³²

Spirochetes may be identified in placental tissue using conventional staining, although they may be difficult to visualize. Nucleic acid amplification methods also have been used to identify *T. pallidum* genome in involved placental specimens.⁵⁰ In addition, the umbilical cord may exhibit significant inflammation, with abscess-like foci of necrosis located within Wharton jelly and centered around the umbilical vessels, which is termed *necrotizing funisitis*.^{46,133} Macroscopically, the umbilical cord resembles a “barber’s pole”; the edematous portions have a spiral striped zone of red and pale blue discoloration, interspersed with streaks of chalky white. Histochemical staining may show spirochetes within the wall of the umbilical vessels. Placental and umbilical cord histopathology should be performed on every case of suspected syphilis.¹³³

PATHOGENESIS AND IMMUNE RESPONSE

The host immune response to syphilis is vigorous and is responsible for many of the clinical manifestations seen in the disease. Despite this immune response, the infection may persist for life. In addition, prior infection does not confer resistance to reinfection. Researchers continue to try to explain this contradiction.¹⁰⁷

Treponemal Virulence–Associated Factors

Virulent *T. pallidum* attaches to host cells during parasitism and is oriented by the proximal hook to the host cell surface. There seems to be a ligand-receptor adherence mechanism involving the treponemal outer membrane proteins. Virulent strains attach to metabolically active mammalian cells, and treponemes are capable of multiplication only during attachment. Fetal and infant cells seem to support treponemal growth maximally, and capillary cells are the prime target of parasitism. Virulent treponemal strains produce hyaluronidase, which may facilitate the perivascular infiltration that is apparent by histopathologic study. These strains also may invade the ground substance that joins capillary endothelial cells.

Virulent *T. pallidum* is coated with fibronectin of host origin. This coating seems to protect the organism from antibody-mediated phagocytosis; allows the organism to adhere to the surface of host phagocytes with only limited ingestion of the organisms; may block complement-mediated lysis of the coated treponemes; and, finally, may allow the treponemes additionally to acquire physiologically active host proteins, such as ceruloplasmin and transferrin, on which they are dependent.¹⁰⁸

FIG. 144.2 Maternal treatment history of 451 cases of congenital syphilis (CS) reported in 2002. (From Centers for Disease Control and Prevention. Congenital syphilis—United States, 2002. *MMWR Morb Mortal Wkly Rep.* 2004;53:716-719.)

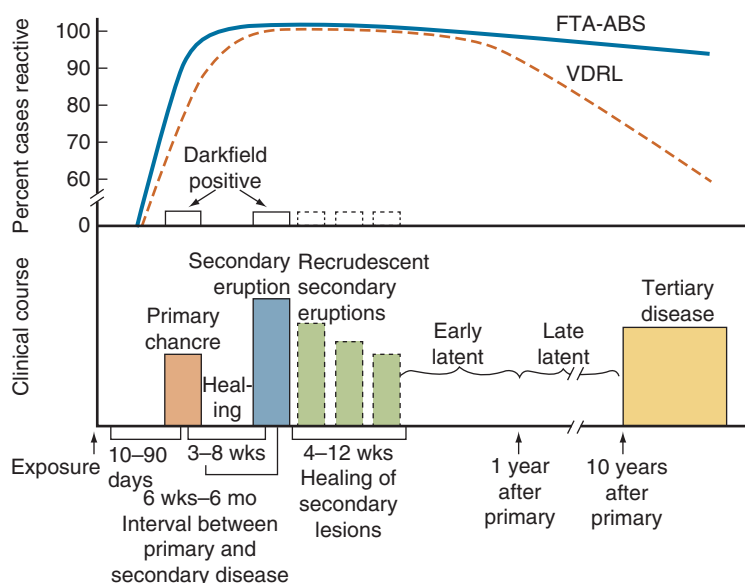

FIG. 144.3 The course of untreated syphilis. FTA-ABS, Fluorescent treponemal antibody absorption; VDRL, Venereal Disease Research Laboratory.

Host Response

Treponemes seem to persist in extracellular loci with little or no inflammatory response elicited. Polymorphonuclear leukocytes ingest virulent treponemes, incorporate them into phagocytic vacuoles, degranulate, and digest *T. pallidum*. In addition, phagocytosis occurs slowly and is facilitated by the presence of immune serum.⁴ Large numbers of treponemes are needed to elicit this response, however, and small numbers may escape recognition.⁹⁴ Although there are few surface-exposed transmembrane proteins, one more recently described, Tpr K, seems to act as a porin.²⁶ It has been shown to elicit an opsonic antibody response in the rabbit model. Variable regions of the protein are explained by diversity in the encoding genes. This antigenic variation could explain the success of the treponeme in evading the host response.^{25,78,92} Innate immunity through toll-like receptor 4 is activated by lipoproteins under the outer membrane and may be important in orchestrating the overall immune response to *T. pallidum*.^{17,114,123}

Alterations in host cell-mediated immunity occur during primary and secondary stages of syphilis. During early stages of disease, all aspects of cell-mediated immunity, including responses to nonspecific T-cell mitogens, are suppressed. Blastogenesis to treponemal antigens is not demonstrable until late in the course of secondary disease. Natural killer cell activity is increased during early primary syphilis and depressed in secondary and latent syphilis.⁶⁴ Some evidence supports the idea that lymphocytes from previously infected animals confer moderate protection to nonimmune animals. In human disease, CD4⁺ T cells and macrophages predominate in primary chancres, whereas CD8⁺ cells predominate in secondary syphilis lesions. In primary and secondary syphilis lesions, helper T cell type 1 (Th1) cytokines are present.^{110,123,145} Some investigators have suggested that increased apoptosis of peripheral blood lymphocytes and CD4⁺ cells by a Fas-mediated pathway that occurs during the secondary stage of infection may explain the failure to clear the organism and set up a chronic infection.³⁹ Alterations in the immune environment of the mother during pregnancy may alter the balance of containment of the organism, allowing transplacental passage to the fetus.¹⁵⁴

During the initial infection with *T. pallidum*, humoral IgG and IgM antibodies are detectable by the time the chancre appears. In primary syphilis, the main IgG subclass is IgG1, whereas IgG1 and IgG3 predominate in secondary syphilis.⁸ If the patient is treated adequately, IgM antibody declines during the next 1 to 2 years, but IgG antibody usually persists through the lifetime of the patient. The stages of syphilis evolve, despite humoral antibody response.

Individuals with untreated syphilis have only a relative resistance to reinfection, so the development of a chancre with reinfection is unusual and probably depends on the challenge inoculum. After reexposure, untreated individuals may develop an increased humoral antibody level.

In individuals who have been treated for syphilis, especially if treatment was provided during the secondary or earlier stages, the protective effect of prior disease is minor, and active disease frequently occurs after reinfection, regardless of whether the patient maintains a reactive nontreponemal antibody test (serofast) or is sero-nonreactive. Patients who have been treated for congenital syphilis also may acquire symptomatic disease.^{43,106} Although active or prior syphilis modifies the response of a patient to subsequent reinfection, protection is only relative and is unreliable.

Secondary syphilis and congenital infection may be accompanied by the nephrotic syndrome. The nephrosis characteristically responds rapidly to penicillin, and light microscopy reveals membranous glomerulonephritis with glomerular mesangial cell proliferation. The subendothelial basement membrane deposits contain IgG and C3 or only globulin. Acute syphilitic glomerulonephritis seems to be an immune complex disease.^{16,49,67} In infants with congenital syphilis, analysis of circulating immune complexes using immunoblotting methods showed the presence of an 83-kDa *T. pallidum* antigen.³⁶ Findings have been similar with secondary syphilis.

CLINICAL MANIFESTATIONS

The course of untreated syphilis characteristically progresses through three or four stages over many years. Information on the natural history of untreated syphilis comes primarily from follow-up studies of almost

2000 untreated syphilitic patients who were seen initially between 1891 and 1910 in the clinic of Boeck. The subsequent studies of these patients by Bruusgaard and by other epidemiologists later provided the basis for most of our concepts of the consequences of syphilis. Clark and Danbolt²⁹ published a summary of some of these studies. Fig. 143.3 depicts some of the characteristics of an untreated course of disease.

Acquired Syphilis

Most recognized syphilitic disease in children is congenital. Acquired syphilis in prepubertal children seldom is reported and is assumed to resemble the clinical course of acquired syphilis in adulthood. Children with acquired syphilis should be assumed to have been infected through contact during child sexual abuse, unless another method of transmission is identified. All patients with syphilis should be tested for HIV infection.²⁴

The decision to screen for syphilis during the medical evaluation of a child who is suspected of having been sexually abused should be made on an individual basis. Situations in which screening is recommended include the following: the perpetrator has an STI or is at high risk for having one, such as residing in a community or being of a social setting in which the prevalence of STIs is high; multiple perpetrators are involved; the child is infected with another STI, such as HIV infection, or has physical signs of sexual abuse; STIs have been diagnosed in siblings, other children, or adults in the household; the patient is postpubertal; or screening is a matter of patient or family preference.^{11,75,134,135} Darkfield examination of chancre fluid, if present, should be performed, as well as serologic tests at the time of abuse and 6, 12, and 24 weeks later because the initial test may not detect incubating syphilis.

Primary Disease

The chancre of primary syphilis typically is a single reddish lesion, nontender and firm, with a clean surface and raised border. It may be overlooked by women because it frequently is situated on the cervix or vaginal wall. Systemic signs or symptoms are absent, but adjacent lymph nodes frequently are enlarged and nontender. Gutman⁵⁴ provides depictions of children with acquired primary syphilis.

Secondary Disease

The patient may experience secondary disease 2 to 10 weeks after the primary lesions manifest. Prominent findings include fever, sore throat, muscle aches, generalized lymphadenopathy, headache, and rash. The palms and soles frequently are involved, in contrast to many other dermatologic conditions. On mucous membranes, the lesions may appear as white mucous patches. Condylomata lata occur around moist areas, such as the anus and vagina. All secondary lesions of the skin and mucous membranes are highly infectious. In their review, Baughn and Musher⁹ give a full description of the manifestations of secondary syphilis. Acquired syphilis in early childhood may reveal minimal dermal findings.¹

Latent Disease

After the clinical signs of secondary disease resolve, the patient enters the stage of latent disease. *Latent syphilis* refers to infection in individuals who have reactive serologic tests for syphilis but no clinical manifestations. The first year after infection is considered *early latent infection*, and the subsequent period is considered *late latent syphilis*. Early latent syphilis originally was classified as syphilis occurring within 4 years of the acquisition of infection, based on the time when mucocutaneous lesions may recur. More recent classification of early latent syphilis is based on the time period of highest communicability, which is in the first year after infection is acquired. Treponemes still can be present in the blood intermittently, however, and pass across the placenta to the fetus during latent syphilis in a pregnant woman.

If the duration of infection with syphilis cannot be determined, the disease is classified as syphilis of unknown duration; clinical management and treatment should be the same as that for late latent infection. If therapy for syphilis is given first during the latent stage, the patient is unlikely to show regression of nontreponemal antibody determinations. Approximately 60% of untreated patients in the late latent stage continue to have an asymptomatic course, whereas 30% to 40% develop symptoms of late or tertiary disease. Progression of disease from late latent to late symptomatic syphilis usually is prevented if appropriate antimicrobial

therapy is given at this stage. The reader is referred to the article by Gutman⁵⁴ for depictions of children with acquired secondary syphilis.

Tertiary Disease

Three to 10 years after the last evidence of secondary disease has occurred, the patient may develop nonprogressive, localized nodules of the dermal elements or supporting structures of the body, called *gummas*. These nodules are granulomatous and can have central necrosis. Because these lesions are relatively quiescent, the term *benign tertiary syphilis* often is used. Spirochetes are extremely sparse or absent. The gummatous reaction is primarily a pronounced immunologic reaction of the host.

Neurosyphilis

During the early stage of syphilis, approximately one-third of all patients have involvement of the CNS. If untreated, only half of these patients develop late neurosyphilis. The interval between primary disease and late neurosyphilis usually is more than 5 years. Of the few children recognized to have acquired (vs. congenital) late neurosyphilis, several have developed symptomatic disease at a very early age. It is possible that the disease progresses more rapidly in children than in adults.

Late neurosyphilis may be asymptomatic or, if symptomatic, may occur in a variety of ways. Classic presentations include paralytic dementia, tabes dorsalis, amyotrophic lateral sclerosis, meningovascular syphilis, seizures, optic atrophy, and gummatous changes of the cord. Neurosyphilis may resemble virtually any other neurologic disease.

Cardiovascular Syphilis

Ten to 40 years after having primary syphilis, an untreated patient may develop signs of cardiovascular involvement. Most frequently involved are the great vessels of the heart, where syphilitic aortic and pulmonary arteritis develop. One complication of this development is aortic regurgitation. The inflammatory reaction also may cause stenosis of the coronary ostia, with resulting angina, myocardial insufficiency, and death.

Syphilis in Pregnancy

Pregnancy has no known effect on the clinical course of syphilis. Untreated syphilis can affect profoundly the outcome of the pregnancy, however, resulting in spontaneous abortion, stillbirth, nonimmune hydrops fetalis,^{6,18} premature delivery, perinatal death, or two characteristic syndromes of congenital disease, early and late congenital syphilis (see later discussion).^{53,125} The outcome of untreated fetal infection varies. Intrauterine death occurs in an estimated 25% of infections, with abortion usually occurring after the first trimester. Perinatal death may occur in another 25% to 30% of untreated infected infants.⁹⁷ In a study of the perinatal outcome of congenital syphilis, the fatality rate was 464 per 1000 infected births. Of the fatalities, 27% were neonatal deaths and 73% were stillbirths.¹²¹ Currently, most infected infants, if not hydropic at birth, survive the neonatal period, most likely because of early identification and treatment of infected infants and improved neonatal care.

The investigations of Taber and Huber¹⁴³ illustrate the importance in pregnant women of recognition of the disease and administration of appropriate therapy. In this study, 22 women with syphilis were undiagnosed during pregnancy and did not receive prenatal therapy. Eleven infants were followed without initial therapy. At delivery, all were asymptomatic clinically, four had a reactive Venereal Disease Research Laboratory (VDRL) test, five had a nonreactive VDRL test, and two were not tested. All these infants were readmitted with obvious disease involving multisystem infection, three with proven spirochetal hepatitis, two with nephrotic syndrome, and three with CNS involvement. This experience emphasizes the importance of recognition of transmission of infection late in gestation, leading to delivery of infants who are well clinically but whose disease emerges in the weeks after delivery if untreated.³⁸

Congenital Syphilis

At the onset of congenital syphilis, *T. pallidum* is liberated directly into the circulation of the fetus, resulting in spirochetemia with widespread dissemination. The clinical, laboratory, and radiographic abnormalities of congenital syphilis are a consequence of active infection with *T. pallidum* and the resultant inflammatory response induced in various body organs and tissues. The severity of these manifestations varies

and can range from overwhelming involvement of multiple organs and body systems, as is seen in fetal hydrops, to only laboratory or radiographic abnormalities. Most of the infants born to mothers with untreated syphilis seem completely normal at birth and have no clinical or laboratory evidence of infection at birth. These infants may develop manifestations of disease several months to years later if left untreated.²⁸ The signs and symptoms of congenital syphilis are divided arbitrarily into early manifestations, which appear in the first 2 years of life, and late manifestations, which emerge at any time thereafter, usually near puberty.

Early Congenital Syphilis

The abnormal physical and laboratory findings in early congenital syphilis are varied and unpredictable.¹¹⁵ Table 144.3 lists the major physical and laboratory findings from 310 reported cases of early congenital syphilis.^{33,67,77,103,121,143} These results undoubtedly are minimal rates for each finding. The onset occurs between birth and approximately 3 months of age, with most cases occurring within the first 5 weeks of life.

Skeletal system. Bone involvement is the most common manifestation of congenital syphilis, occurring in 60% to 80% of infants with clinical signs of syphilis. In addition, it may be the only abnormality seen in infants born to mothers with untreated syphilis. Because of their frequency and early appearance, the radiographic changes in the bones, termed *osteochondritis* and *periostitis*, are of diagnostic value.³³ The femur and humerus are involved most often. Radiographically, accumulating calcified matrix is seen at the epiphyseal margin, which may be smooth or serrated. The serrated appearance is known as *Wegner sign* and represents points of calcified cartilage along the nutrient cartilage canal.

A zone of rarefaction at the metaphysis that represents syphilitic granulation tissue containing a few scattered calcified remnants and a mass of connective tissue containing areas of perivascular infiltration of small round cells may be seen. Irregular areas of increased density and rarefaction produce the moth-eaten appearance of the radiograph. The demineralization and osseous destruction of the upper medial tibial metaphysis are called *Wimberger sign*. Previously thought to be specific for syphilis, Wimberger sign also may occur in osteomyelitis and hyperparathyroidism. Epiphyseal separation may occur as a result of a fracture of the brittle layer of calcified cartilage. Irregular periosteal thickening also is a common finding. The changes usually are present at birth but may appear in the first few weeks of life. The bony changes are self-limited and usually are healed in the first 6 months, even in the absence of specific therapy. They may be painful lesions, and pain on motion often leads an affected infant to appear to have a limb paralysis, termed *pseudoparalysis of Parrot*.

TABLE 144.3 Findings in 310 Cases of Early Congenital Syphilis

Findings	No. Patients
Hepatomegaly	100
Skeletal abnormalities	91
Birth weight <2500 g	51
Skin lesions	45
Hyperbilirubinemia	40
Pneumonia	51
Splenomegaly	56
Severe anemia, hydrops, edema	50
Snuffles, nasal discharge	27
Painful limbs	22
Pancreatitis	14
Cerebrospinal fluid abnormalities	21
Nephritis	11
Failure to thrive	10
Testicular mass	1
Chorioretinitis	1
Hypoglobulinemia	1

Data from references 41, 76, 89, 91, 95–98.

Rhinitis. Rhinitis, coryza, or snuffles are likely to mark the onset of congenital syphilis. Usually, it appears in the first week of life and seldom later than the third month. The snuffles are more severe and persist longer than the common cold. The nasal discharge is white and often bloody, and the snuffles frequently are associated with laryngitis. Secondary bacterial superinfection may result in a purulent appearance. The nasal discharge is teeming with spirochetes and should be examined by darkfield microscopy to confirm its diagnosis.

Rash. The syphilitic rash usually appears 1 to 2 weeks after rhinitis manifests. The typical eruption is maculopapular and consists of small spots that are dark red-copper. If the rash is present at birth, it often is widely disseminated and bullous and is called *pemphigus syphiliticus*. It is most severe on the hands and feet. The bullous fluid contains many spirochetes. The rash erupts slowly, taking 1 to 3 weeks, and is followed by desquamation and crusting. As the rash fades, the lesions become coppery or dusky red, and pigmentation may persist. The reader is referred to the article by Gutman³⁴ for depictions of a variety of cutaneous manifestations of early congenital syphilis.

Fissures and mucous patches. Fissures and mucous patches are not seen often but are highly characteristic features of congenital syphilis. The fissures develop around the lips, nares, and anus. They bleed readily and heal with scarring. A cluster of scars radiating around the mouth is called *rhagades* and is a characteristic of late congenital syphilis. Mucous patches may be found on any of the mucous membranes, especially in the mouth and genitalia. Condylomata lata are raised, moist lesions appearing on areas of the skin where there is moisture or friction. They are highly infectious because they contain many spirochetes.

Hematologic findings. Congenital syphilis is characterized by anemia, thrombocytopenia, hemolytic processes, and leukopenia and leukocytosis.⁷⁷ The hemolytic process is Coombs test negative and often accompanied by cryoglobulinemia, immune complex formation, and macroglobulinemia. The hemolysis, similar to the liver disease, is refractory to therapy and may persist for weeks. Paroxysmal nocturnal hemoglobinuria is a late manifestation of congenital syphilis.

Central nervous system involvement. In the era before the introduction of penicillin therapy, approximately 15% of infants with congenital syphilis developed manifestations of meningovascular disease. These findings included meningitis, meningeal irritation, bulging fontanelle, cranial nerve palsies, seizures, and hydrocephalus.⁶¹ In addition, involvement of the pituitary gland in congenital syphilis is a common manifestation, occurring in approximately 40% of autopsy cases,¹⁰³ and consists of interstitial inflammation and fibrosis with formation of gumma in the anterior lobe. Clinical disease in affected infants is manifested by persistent hypoglycemia and diabetes insipidus.^{34,101}

Most infants infected with *T. pallidum* are completely symptom free, and involvement of the CNS is inferred from abnormalities of the cerebrospinal fluid (CSF), such as reactivity on a VDRL test, pleocytosis, and elevated protein content. Because of the wide range of normal values for CSF protein, red blood cells, and white blood cells in the neonatal period, defining the proportion of infants with congenital syphilis who have abnormalities of these laboratory values has been difficult. Current consensus identifies an abnormal CSF white blood cell count in infants being evaluated for possible congenital syphilis as greater than 25 cells/mm³ and protein as greater than 150 mg/dL (>170 mg/dL if infant is premature). A reactive CSF VDRL test is considered to be specific for neurosyphilis in older children and adults. In neonates, the significance of a reactive CSF VDRL test is suspect, however, because maternal nontreponemal IgG antibodies can pass from maternal serum to fetal and neonatal serum and then diffuse into the CSF. Children may fail to have a reactive VDRL test on initial examination and still develop later signs of neurosyphilis.

Using rabbit infectivity testing, which involves the inoculation of CSF into rabbits to determine the presence of the spirochete in the CSF specimen, Michelow and coworkers⁹¹ found that invasion of the CNS with *T. pallidum* occurs in 41% of infants who have clinical, laboratory, or radiographic abnormalities of congenital syphilis. None of these infants had clinical signs of neurologic disease. Compared with isolation of spirochetes in CSF by rabbit inoculation, the sensitivity and specificity in CSF of a reactive VDRL test, elevated white blood cell count, and elevated protein were 54% and 90%, 38% and 88%, and 56% and 78%,

respectively. These investigators also documented CNS infection in three infants who had normal CSF studies. Using current methods, the best indicator of CNS infection in neonates is an abnormal evaluation consisting of abnormal findings on physical examination, anemia, thrombocytopenia, CSF abnormalities, and abnormal bone radiographs. A normal evaluation renders CNS infection rare.

Pneumonia. Syphilitic pneumonia is a common occurrence in congenital syphilis, particularly in developing countries. The classic radiographic appearance is one of complete opacification of both lung fields and is termed *pneumonia alba*. More commonly today, a fluffy, diffuse infiltrate involving all lung areas is seen on the chest radiograph. At autopsy, pneumonia alba consists of a focal obliterative fibrosis with scarring and thickening of alveolar walls and loss of alveolar spaces. Follow-up evaluation of children who have recovered from congenital syphilis has shown that at least 10% may have chronic pulmonary disease, particularly if they were premature and required mechanical ventilation.

Hepatosplenomegaly. Hepatomegaly is the most common clinical sign in congenital syphilis. Its occurrence in the fetus has been documented by ultrasonography, and it may be a marker of inadequate treatment of the fetal infection despite maternal treatment during pregnancy.⁵⁸ Hepatosplenomegaly often is caused by extramedullary hematopoiesis. Hepatomegaly may occur in the absence of splenomegaly; but in contrast to congenital cytomegalovirus, the reverse does not. Neonatal syphilitic hepatitis is associated with visible spirochetes on biopsy specimens of liver tissue, jaundice, and cholestasis. Aspartate aminotransferase, alkaline phosphatase, and alanine aminotransferase determinations often are elevated, and direct hyperbilirubinemia is a common finding. The prothrombin time may be delayed. The liver disease often resolves slowly, even after administration of apparently adequate therapy, and may be exacerbated by penicillin therapy before improving.¹³¹

Ectodermal changes. Ectodermal changes in syphilitic infants include suppuration and exfoliation of the nails, loss of hair and eyebrows, choroiditis, and iritis.

Other findings. Other clinical manifestations of congenital syphilis include nonimmune fetal hydrops, possibly intrauterine growth restriction, generalized lymphadenopathy, fever, failure to thrive, nephrotic syndrome, and myocarditis. Involvement of the eyes has been manifested by chorioretinitis, cataract, glaucoma, and chancre of the eyelid. Gastrointestinal presentations include rectal bleeding caused by syphilitic ileitis, necrotizing enterocolitis, malabsorption secondary to fibrosis of the gastrointestinal tract, and fetal bowel dilation seen on antenatal ultrasonography.^{116,121} Some children with symptomatic congenital syphilis also may have sepsis caused by other bacteria, including *Escherichia coli*, group B streptococci, and *Yersinia* spp. Neonates and infants with congenital syphilis may resemble infants with other illnesses peculiar to neonates, including toxoplasmosis, rubella, cytomegalovirus infection, herpes simplex virus infection, "sepsis" of the newborn, blood group incompatibilities, battered child syndrome, "periostitis" of prematurity, neonatal hepatitis, and osteomyelitis.

Late Congenital Syphilis

Late manifestations or stigmata of congenital syphilis are the result of scarring from the early systemic disease or reactions to persistent inflammation and include involvement of the teeth, bones, eyes, and eighth cranial nerve; gummas in the viscera, skin, or mucous membranes; and neurosyphilis (Table 144.4).⁴⁵ Approximately 40% of surviving and untreated infected infants, as reported in the early literature, develop late manifestations of infection. Some of these changes can be prevented by treating the mother during pregnancy or the infant before the child reaches 3 months of age. In contrast, treatment of 15 children at 4 months of age or later showed seven with dental changes.¹¹¹ Other stigmata (e.g., keratitis, saber shins) may occur or progress, despite the infants being administered appropriate therapy. Nonspecific sequelae of congenital syphilis have not been described well because follow-up studies of children with congenital syphilis are minimal. It has been the experience of one of the authors (P.J.S.), however, that infants who are diagnosed with congenital syphilis and treated appropriately in the neonatal period generally do well at least through early childhood. There is every reason to be hopeful and optimistic with the families of these children, even if they are symptomatic and have CNS involvement at the time of diagnosis.

TABLE 144.4 Stigmata of Late Congenital Syphilis^a

Stigmata	Percentage of Total Patients
Frontal boss of Parrott	87
Short maxilla	84
High palatal arch	76
Hutchinson triad	75
Higouménakis sign	73
Relative protuberance of mandible	65
Saddle nose	63
Interstitial keratitis	39
Rhagades	26
Mulberry molars	9
Saber shin	7
Eighth nerve deafness	4
Hutchinson teeth	3
Scaphoid scapulae	0.7
Clutton joint	0.3

^aAnalysis of 271 patients.Modified from Fiumara NJ, Lessell S. Manifestations of late congenital syphilis. *Arch Dermatol.* 1970;102:78-83.

Dentition. Characteristic changes are found in the permanent upper central incisors, which have a notched appearance of the biting edges; radiographic study leads to diagnosis, even while deciduous teeth are in place. These are Hutchinson teeth, which also are small and hypoplastic and widely spaced with abnormal enamelization. If first molars show maldevelopment of the cusps, the finding is called *mulberry* or *moon molars*.

Interstitial keratitis. Interstitial keratitis is the most common late lesion. It may appear at any age between 4 and 30 years or later but characteristically appears when the patient is close to puberty. A ground-glass appearance may develop in the cornea, accompanied by vascularization of the adjacent sclera. These changes become bilateral and usually lead to blindness. It has been seen in adolescent patients despite their having received previous and appropriate penicillin therapy during infancy. At the time of its occurrence, keratitis is not affected by penicillin therapy, but it may respond transiently to corticosteroid treatment.

Central nervous system. The same manifestations of neurosyphilis seen in acquired syphilis may occur in congenital syphilis. Paresis is seen more frequently and tabes dorsalis less frequently in the congenital form than in the acquired form of the disease. Cranial nerve palsies and optic atrophy are prominent.

Eighth cranial nerve deafness. Hearing loss usually is sudden and occurs when the child reaches 8 to 10 years of age. It often accompanies interstitial keratitis. The constellation of eighth cranial nerve deafness, interstitial keratitis, and Hutchinson teeth is called the *Hutchinson triad*. The hearing loss usually involves the higher frequencies, and normal conversational tones become affected later. This hearing loss may respond to long-term corticosteroid treatment.

Bone and joint changes. Bone changes include the sclerosing lesions, saber shin, and frontal bossing, which are sequelae of periostitis that involved the frontal bone and tibia. Periosteal reaction of the sternoclavicular portion of the clavicle may lead to swelling, known as the Higouménakis sign. The gummatous or destructive lesions include saddle-nose deformity, which occurs as a sequela of rhinitis. Perforation of the hard palate is almost pathognomonic of congenital syphilis. Clutton joints are uncommon findings and represent painless arthritis of the knees and, rarely, other joints.

Cutaneous lesions. Rhagades represent scars resulting from persistent rhinitis during infancy and rarely are seen today.

DIAGNOSIS

The vagaries of the maternal history and signs or lack of signs in the infant at birth (i.e., timing of the mother's initial syphilis infection

before or during pregnancy, adequacy and documentation of her treatment, an infant who is infected and symptomatic at birth, an infant who is asymptomatic at birth but may not remain so because infection has occurred, and an infant who is asymptomatic and not infected) demand a "safety first" approach to diagnosis and treatment. Efforts to diagnose infectious syphilis suffer from the lack of a method to culture the organisms on laboratory media. Methods that are used in establishing the diagnosis of syphilis include (1) direct visualization of the organism by darkfield microscopy or fluorescent antibody technique of infected fluids or lesions, (2) demonstration of the organism by special stains on histopathologic examination of tissue,^{56,119} (3) animal inoculation (rabbit infectivity test), (4) demonstration of serologic reactions typical of syphilis, and (5) detection of *T. pallidum* DNA in a clinical specimen.²⁰

The rabbit infectivity test is still the gold standard for the identification of viable *T. pallidum* in clinical specimens, having a sensitivity of less than 10 organisms.^{84,85} It involves intratesticular inoculation of the specimen into a rabbit and awaiting serologic seroconversion and orchitis with subsequent visualization of motile spirochetes by darkfield microscopy in testicular tissue. The rabbit infectivity test is performed only in research laboratories and may take several months for identification of the organism. *T. pallidum* DNA has been detected by polymerase chain reaction (PCR) in body fluids such as amniotic fluid and infant blood, CSF, and endotracheal aspirate.^{52,91} The new genetic information about *T. pallidum* may lead to development of novel diagnostic tools.

In the clinical setting, the diagnosis of syphilis is established by visualization of the spirochete by darkfield microscopy or special staining and serology. Patients with a primary syphilis lesion (chancre) and with active secondary lesions may be diagnosed by darkfield microscopy. Because this diagnosis depends on direct visualization of motile spirochetes, the organisms must be active and viable. Prior use of many antibiotics rapidly destroys the motility of the organisms, as do many topical disinfectants. Serous fluid from the base of the lesion should be collected for darkfield examination. Syphilitic lesions of the mouth may harbor indigenous treponemes, of which the morphologic similarity to pathogenic species can confuse the interpretation of findings.

Direct darkfield examination is particularly helpful in establishing a diagnosis early in the course of the disease, before the development of seroreactivity. If a darkfield microscope is unavailable, a direct fluorescent antibody stain for *T. pallidum* may be made.¹⁸ Exudate is collected in capillary tubes or slides and stained with specific antibody. Amniotic fluid may be examined for the presence of spirochetes using darkfield microscopy or fluorescent antitreponemal staining; the finding of spirochetes may be a marker for more severe fetal disease.^{51,148} On a practical basis, however, the diagnosis is established by serologic methods.^{81,150}

Serologic Tests

The two types of serologic tests for syphilis are the nontreponemal antibody tests and the treponemal antibody tests (Table 144.5). Although the latter tests indicate experience with a treponemal infection in the past, they cross-react with the antigens of other treponemal diseases, such as the antigens causing yaws and pinta. No test is specific for syphilis, and no test is completely sensitive. Efforts to produce a more sensitive and more specific test are continuous. A promising approach is the use of recombinant clones expressing immunogenic proteins of *T. pallidum* to investigate pathogen-specific antigens.⁶³ Some of these products are being investigated for use as diagnostic material.¹²⁷

Point of care testing is becoming a feasible reality for low resource settings, usually linked to HIV testing using immunochromatographic strips. These tests can be done during antenatal visits, do not require the laboratory infrastructure necessary for conventional tests, and can be performed on fingerstick blood samples. They are easy to perform, results are easily interpreted, and there is a quick turnaround time of 20 minutes or so. They have good sensitivity and specificity, comparable to those of conventional treponemal and nontreponemal tests.^{15,74}

Nontreponemal Tests

The original test for syphilis, as described by Wassermann, used syphilitic tissue as complement-fixing antigen to detect the presence of antibody

TABLE 144.5 Standard Serologic Tests for Syphilis

		SENSITIVITY BY STAGE OF INFECTION (%)				
Type	Test	Primary	Secondary	Latent	Late/Tertiary	Specificity (%)
Nontreponemal						
Extracts of tissue (cardiolipin-lecithin-cholesterol)	VDRL	78	100	96	71	98
	RPR	86	100	98	73	98
Treponemal						
Treponema pallidum	MHA-TP ^a	76	100	97	94	99
	FTA-ABS	84	100	100	96	97
	EIA	100	100	100	-	99
	CIA	98	100	100	100	99

^aMHA-TP has been replaced with *Treponema pallidum* particle agglutination (TP-PA) test.

CIA, Chemiluminescence immunoassay; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption; MHA-TP, microhemagglutination assay–*Treponema pallidum*; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

Modified from Seña AC, White BL, Sparling PF. Novel *Treponema pallidum* serologic tests: a paradigm shift in syphilis screening for the 21st century. *Clin Infect Dis*. 2010;51(6):700-708.

(reagin) that is induced by *T. pallidum*. Extracts of other normal tissue, such as beef heart, had similar properties, and purification and standardization of these materials led to the use as antigen of a preparation containing cardiolipin and lecithin in cholesterol.

Two tests currently using cardiolipin, lecithin, and cholesterol are the VDRL and rapid plasma reagin (RPR) tests. These tests measure mostly IgG, but also IgM antibodies nondiscriminatively. The tests provide similar clinical information and have similar advantages. The RPR titer often is one to two dilutions higher than the titer obtained using the VDRL test, so caution must be exercised when making clinical decisions on the basis of results obtained from these two tests performed on the same patient. Both are inexpensive to perform and show increasing and decreasing antibody titers that often correlate with adequacy of therapy and the clinical status of a patient. A fourfold increase in RPR or VDRL titers indicates active disease, whereas a fourfold decrease suggests adequate therapy. Disadvantages include a high proportion of biologic acute and chronic false-positive reactors and an increasing proportion of false-negative reactions in the later stages of untreated syphilis. The main technical difficulty is a negative reaction owing to the prozone phenomenon, which occurs in 1% to 2% of individuals, usually patients with secondary syphilis, and is due to an excess amount of reagin antibody present in the patient's undiluted serum that prevents flocculation. Diluting the serum sample before testing overcomes the inhibition and results in the positive reaction. Because the RPR test generally is more sensitive than is the VDRL test, it is preferred for screening pregnant women. The VDRL test is recommended for use on CSF, however.

The RPR test is used frequently to screen pregnant women for possible infection with *T. pallidum*. Transplacental passage of IgG antibodies to the infant means that mothers with reactive RPR tests usually transmit these antibodies to their infants. Taber and Huber³⁰ reviewed the relationship of maternal to newborn VDRL tests in their study of mothers who were undiagnosed and untreated. Although 12 of 22 mothers had VDRL test results two to four times that of their infants, 6 of these women and their infants had nonreactive serology at the time of delivery. These and other data showed that it was unusual for an infant to have a VDRL test of greater titer than the mother's, even if the infant was incubating congenital syphilis.¹³⁹ Nonetheless, the finding of a titer in the infant serum fourfold higher than that seen in the maternal serum when both are obtained at the same time is indicative of active infection in the infant. Even if the infant is asymptomatic, a 10-day course of penicillin therapy should be administered.

Treponemal Tests

The most significant development of the past 4 decades in the serologic study of syphilis was the detection of treponemal antibody by fluorescein-labeled antihuman antibody and indirect agglutination. These tests are used to confirm the validity of a positive nontreponemal test and to diagnose late stages of syphilis. The tests are sensitive and reliable. More recently, newer versions of these tests, such as the *T. pallidum* enzyme

immunoassay (TP-EIA) and chemiluminescence immunoassay (CIA), have been automated, enhancing simplicity and ease of use. As a result, the TP-EIA and CIA tests are increasingly used to screen for syphilis rather than as confirmatory tests with a reversal in the order of testing so that a positive treponemal immunoassay test requires confirmation using the nontreponemal tests (reverse sequence screening).¹³⁰

The advantages and disadvantages of this reversal of the usual testing algorithm and how it is being used in the WHO elimination of mother to child transmission of syphilis is well summarized in a recent review.⁷⁴

Fluorescent treponemal antibody absorption (FTA-ABS) tests use lyophilized Nichols strain organisms as antigen and measure IgG and IgM antibodies. Antigen is fixed to a slide, and the test serum is applied, allowing reaction of antitreponemal antibody with antigen to occur. The slide is layered with fluorescein isothiocyanate–labeled antihuman gamma globulin, and the presence or absence of antibody is determined by fluorescent microscopy.

Test sera are preabsorbed with sorbent to eliminate group-reactive antibody. The test is rendered specific for disease with virulent treponemal species, usually *T. pallidum*. The FTA-ABS test is expensive and time-consuming, however. It is recommended not for general screening but for confirmation of positive nontreponemal tests and for establishing the diagnosis of later stages of syphilis in which the results of nontreponemal tests may be negative.

Microhemagglutination tests, and specifically the *T. pallidum* particle agglutination (TP-PA) test, depend on the passive hemagglutination of erythrocytes or latex particles that have been sensitized with Nichols strain *T. pallidum*. The test has been automated and is easy to perform technically and inexpensively. The TP-PA test has largely replaced the FTA-ABS test as the most efficient specific test for antibody to *T. pallidum*. The TP-PA test is as sensitive as is the FTA-ABS test, except in primary syphilis. The test is positive in 75% to 85% of patients with primary syphilis and in 100% of patients with secondary syphilis. Similar to the FTA-ABS test, the TP-PA test is unlikely to revert to a nonreactive state after treatment of the patient, unless treatment is given very early.

IgM Tests

In the diagnosis of congenital syphilis, having a means to differentiate between passive transplacental transfer of maternal antibody to the fetus and production by the fetus of endogenous antitreponemal antibody would be most helpful. Because antibodies of the IgM class do not cross the placenta, detection of IgM antibody in the fetal or neonatal serum would indicate antibody production by the fetus because of active fetal infection. No IgM assay currently is commercially available that is sufficiently sensitive and specific to recommend for routine use in the evaluation of infants born to mothers with syphilis. The fluorescent treponemal antibody that measures IgM antitreponemal antibodies, the IgM-FTA-ABS test, has been associated with false-positive and false-negative results. When the test was refined further by use of the IgM fraction of neonatal serum only, it had a sensitivity of 73%.¹⁴¹ The test also is insensitive when the onset of disease is delayed. Occasional

false-positive IgM-FTA-ABS tests occur because of the presence of an IgM anti-IgG antibody or rheumatoid factor. For these reasons, the CDC has recommended that the IgM-FTA-ABS test be suspended for diagnostic testing of neonates, and the test is available only as a provisional test.

Efforts to develop a sensitive and specific serologic test for congenital syphilis have led to the identification of antigenic components of *T. pallidum* that are epitopes for the immune response. A 34-kDa membrane protein is a dipoprotein¹⁴² and the target of IgM antibody formation in the sera of some congenitally infected infants.³⁷ The Captia Syphilis-M test is an enzyme-linked immunosorbent assay that uses this treponemal protein; it is commercially available but showed a sensitivity of only 88% among infants with clinical and laboratory findings of congenital syphilis.^{79,141}

Immunoblotting has been used to characterize the specific neonatal IgM antibody responses to *T. pallidum*. Specific IgM antibodies directed against *T. pallidum* antigens with apparent molecular masses of 72, 47, 45, 42, 37, 17, and 15 kDa have been detected in sera of fetuses⁶⁰ and infants with clinical findings of congenital syphilis and in 20% to 40% of asymptomatic infants born to mothers with untreated syphilis.^{37,82,90,124,126,127} IgM reactivity against the 47-kDa antigen, a membrane lipoprotein of the organism, has been the most consistent finding. Similar reactivities also have been seen in CSF of infants with congenital syphilis.^{82,126} One study showed that a reactive serum IgM immunoblot identified all 17 infants in whom spirochetes were detected in their CSF by rabbit infectivity testing.⁹⁰ Efforts to develop rapid diagnostic tests have been based on these findings.⁷⁵ In addition, immunoblotting has been used to detect similar IgA reactivities among infants with congenital syphilis.¹²⁶

Polymerase Chain Reaction Assay

The PCR assay has been used on neonatal blood and CSF for establishing the diagnosis of congenital syphilis.^{52,91,127} Compared with isolation of the organism by rabbit infectivity testing, the sensitivity and specificity of PCR on CSF was 65% to 71% and 97% to 100%, respectively.^{91,124} Among 17 infants who had spirochetes detected in their CSF by rabbit inoculation, blood PCR test was the best predictor of CNS infection with *T. pallidum*.⁹¹ This finding supports further the concept that spirochetes gain access to the CNS by a hematogenous route. Further research is needed on PCR assays that will reliably detect *T. pallidum* DNA in neonatal clinical specimens.

False-Positive Reactions

All of the available serologic tests for syphilis produce occasional reactive results in patients who have no other evidence of syphilitic infection. These reactions usually are called *biologic false-positive* (BFP) reactions and are distinct from positive reactions owing to technical errors. Most BFP reactions occur with nontreponemal tests; approximately 1% of normal adults have a BFP reaction by nontreponemal antigen tests. These reactions probably are more common in pregnant women than in the general population. Reagin antibody is reactive with at least 200 antigens other than those of *T. pallidum*, and although the specific stimulus for this antibody in syphilis and other diseases is unknown, it may represent antibody to cellular lipoidal antigens of the host that are liberated during various diseases. For clinical purposes, BFP reactions may be classified as acute, in which the reactivity resolves within 6 months, or chronic, in which reactivity is persistent.

Acute biologic false-positive reactions. Most BFP reactions are detected by nontreponemal tests and occur in patients with other acute illnesses, especially pneumonia, hepatitis, and viral exanthematous disease, or after receiving vaccinations. The prognosis for the patient's health is not affected by the finding. The titer of antibody usually is low (<1:8), and in most instances the FTA-ABS or TP-PA test is nonreactive. Approximately two-thirds of patients with BFP reactions have acute reactions, and reactivity subsides within 6 months.

Chronic biologic false-positive reactions. Many patients with chronic BFP reactions have or develop systemic disease. Drug addiction, chronic hepatitis, old age, leprosy, and collagen vascular disease, especially systemic lupus erythematosus, are associated highly with chronic BFP reactions. A familial predisposition to this finding may exist. The antibody detected

by the VDRL test in chronic BFP reactions predominantly is IgM, whereas it mainly is IgG in syphilis. Patients with chronic BFP reactions and systemic lupus erythematosus commonly also have a reactive FTA-ABS test.⁸⁰ The triosephosphate isomerase test may be helpful in the differential diagnosis in these instances. A finding of particular concern is that there seems to be a relative increase in acute and chronic BFP reactions in women who are infected with HIV.

Screening with EIA/CIA treponemal tests has resulted in some individuals having a reactive EIA/CIA test but a nonreactive nontreponemal test. If the individual does not have a history of adequately treated syphilis, a second treponemal test (TP-PA preferred) should be performed, and if it is negative, the positive EIA/CIA is more likely to represent a false-positive test.

Evaluation and Diagnosis of Early Congenital Syphilis

The diagnosis of congenital syphilis is suggested by results of serologic tests, physical examination, laboratory tests including CSF examination, and radiographs of long bones and is established by the observation of spirochetes in body fluids or tissue. Examination of the placenta or umbilical cord using specific fluorescent antitreponemal antibody staining is recommended.^{50,112} The decision to evaluate and ultimately to treat an infant for congenital syphilis is based on clinical, serologic, and epidemiologic considerations. The evaluation includes an assessment of the mother for general risk factors for increased rates of syphilis (Box 144.3), followed by an evaluation of the mother's current known serologic status (Box 144.4). If the mother has been treated, the clinician must assess the adequacy of the therapy.

BOX 144.3 General Maternal Risk Factors Associated With Increased Rates of Early Syphilis in Pregnancy

- Infection with HIV
- Adolescent or unmarried status
- History of sexually transmitted disease
- Substance abuse, especially cocaine
- Inadequate or absent prenatal care
- Prostitution or promiscuity
- Localized populations or geographic areas
- Treatment of gonorrhea with ciprofloxacin or spectinomycin
- Poor communication among medical personnel regarding maternal/infant status

Data from references 42, 46, 48, and 49.

BOX 144.4 Components of Epidemiologic Evaluation of a Mother for Possible Syphilis That Aid in Evaluation and Treatment of Her Infant

- Evaluate mother for prior history of syphilis or major risk factors for syphilis (see Box 144.3).
- If mother received treatment for syphilis, evaluate course of therapy for adequacy in the treatment of congenital syphilis (see Box 144.2).
- Evaluate current maternal status with a nontreponemal test (e.g., Venereal Disease Research Laboratory, rapid plasma reagin) and, if reactive, a treponemal test (e.g., fluorescent treponemal antibody absorption, *Treponema pallidum* particle agglutination test).
- If mother is identified clinically or through contact tracing as having early syphilis during the 3 months after delivery, reevaluate the infant and consider therapy at that time.
- Higher maternal titers to nontreponemal tests are associated with failure of maternal therapy to prevent congenital disease.⁸⁹
- Unknown duration of maternal syphilis is associated with failure of maternal therapy to prevent congenital disease.⁸⁹

If the mother's serologic assays have been positive, the infant must be assessed for clinically apparent disease. The nontreponemal (RPR) and treponemal (TP-PA; EIA) tests measure IgG antibody and do not distinguish disease of the infant from maternally derived antibody. Many infants are born to women who have had syphilis in the past, received therapy, and remained seroreactive. Their infants also are seroreactive. Ensuring that the infant does not have congenital disease in the immediate neonatal period may be impossible.

Fig. 144.3 and Table 144.6 present an approach to the evaluation of infants born to mothers with reactive serologic tests for syphilis. Testing of all pregnant women with syphilis for coinfection with HIV is recommended strongly, even though infants born to coinfecting mothers do not require any different evaluation for syphilis.⁷⁹ All infants born to mothers with reactive serologic tests for syphilis should have a serum quantitative nontreponemal test performed and a thorough physical examination that focuses on finding evidence of congenital syphilis. The nontreponemal test that is performed on the infant should be the same as the test done on the mother to be able to compare serologic titers. Although it is an uncommon finding, a serum quantitative

nontreponemal titer that is fourfold or greater than the corresponding maternal titer is diagnostic of congenital syphilis; when it has occurred, one of the authors (P.J.S.) has isolated spirochetes from blood or CSF in all infants.

The CDC recommends that the infant's serologic test be performed on serum and not umbilical cord blood because false-positive test results have been reported with the use of umbilical cord blood secondary to contamination of the specimen with maternal blood and Wharton jelly. Some clinicians continue to use umbilical cord blood, however, because it is readily available and easily collected; appropriate care should be taken during collection to minimize contamination with maternal blood. In addition, false-negative test results may occur when the maternal titer is low dilution, which argues for maternal screening rather than screening of infant serum.

Infants who have (1) an abnormal physical examination that is consistent with congenital syphilis, (2) a serum quantitative nontreponemal serologic titer that is fourfold or greater than the mother's, or (3) a positive darkfield or fluorescent antibody test of body fluid should have a complete blood cell count and platelet count performed and

TABLE 144.6 Treatment Guidelines for Congenital Syphilis

Scenario	Maternal Stage/Treatment	Evaluation	Antimicrobial Regimen
Infant age ≤ 28 d with proven or highly probable disease: (a) Abnormal physical examination (b) Abnormal evaluation ^a (c) Serum nontreponemal titer ≥ 4 times maternal titer (d) Visualization of spirochetes in clinical specimen	Any or none	CSF analysis: VDRL, cell count, and protein; CBC and platelet count; other tests as clinically indicated (e.g., long bone radiographs, liver function tests, ophthalmologic examination, hearing evaluation, neuroimaging)	Aqueous penicillin G 50,000 U/kg IV q12h (≤ 1 wk old), q8h (> 1 wk old, ≤ 4 wk old), q6h (> 4 wk old) $\times 10$ d, <i>or</i> Procaine penicillin G 50,000 U/kg IM $\times 10$ d (≤ 4 wk old)
Infant age ≤ 28 d with possible congenital syphilis: normal physical examination and serum quantitative nontreponemal titer the same or less than fourfold the maternal titer ^b	Any stage of infection and: mother (a) was not treated, inadequately treated, or has no documented treatment; (b) was treated with erythromycin or other nonpenicillin regimen; or (c) received appropriate treatment but ≤ 4 wk before delivery	CSF analysis for VDRL, cell count, and protein; CBC and platelet count; long bone radiographs ^b	If complete evaluation normal: (a) benzathine penicillin G 50,000 U/kg IM $\times 1$ ^c <i>or</i> (b) aqueous penicillin G 50,000 U/kg IV q12h (≤ 1 wk old), q8h (> 1 wk old, ≤ 4 wk old), q6h (> 4 wk old) $\times 10$ days, <i>or</i> (c) procaine penicillin G 50,000 U/kg IM $\times 10$ d (≤ 4 wk old)
Infant age ≤ 28 d with congenital syphilis less likely: normal physical examination and serum quantitative nontreponemal titer the same or less than fourfold the maternal titer	Mother with: (a) adequate therapy > 4 wk before delivery, and appropriate for stage of infection; <i>or</i> (b) nontreponemal titers remained stable and low for late syphilis and no evidence of reinfection or relapse	No evaluation	Benzathine penicillin G 50,000 U/kg IM $\times 1$ (preferred), <i>or</i> Clinical, serologic follow-up
Infant age ≤ 28 d old with congenital syphilis unlikely: normal physical examination and serum quantitative nontreponemal titer the same or less than fourfold the maternal titer	Mother with adequate therapy before pregnancy and nontreponemal serologic titer remained low and stable during pregnancy and at delivery	None	None
Congenital syphilis in infant age > 28 d	Any or none	CSF analysis: VDRL, cell count, protein; CBC and differential; platelet count. As clinically indicated: radiographs of long bones, liver function tests, neuroimaging (cranial ultrasonography), eye examination, hearing evaluation	Aqueous penicillin G, 50,000 units/kg q4–6h $\times 10$ d ^d

^aCSF examination (VDRL test, cell count, protein), bone radiographs, CBC, platelets.

^bIf the infant's nontreponemal test is nonreactive, no evaluation is required, but the infant should receive a single IM dose of benzathine penicillin G 50,000 U/kg.

^cClinical and serologic follow-up must be certain.

^dSome experts prefer prolonged therapy by administration of a single dose of benzathine penicillin G after the 10-day course of IV aqueous penicillin G.

From American Academy of Pediatrics. Syphilis. In: Kimberlin DW, ed. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. American Academy of Pediatrics, Elk Grove Village, IL: American Academy of Pediatrics; 2015:755; and Workowski KA, Bolan GA, CDC. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(RR-3):1-138.

examination of the CSF for cell count, protein content, and VDRL test. Other tests, such as bone and chest radiographs, liver function tests, cranial ultrasonography, ophthalmologic examination, and auditory brainstem response, should be performed as clinically indicated. These infants are considered to have proven or highly probable disease; spirochetemia with invasion of the CNS occurs in 40% to 50% of these infants.¹⁶ Although these infants must receive a full course of penicillin therapy, which treats possible neurosyphilis, it is beneficial for follow-up purposes to establish CNS abnormalities at presentation. Nonetheless, the diagnosis of congenital neurosyphilis is difficult to establish (see [Clinical Manifestations](#)). The presence of red blood cells in the CSF as a result of a traumatic lumbar puncture can produce a false-positive serologic reaction. Examination of the CSF for *T. pallidum* DNA by PCR may prove more useful for diagnosing congenital neurosyphilis.^{52,91,127}

For infants who have a normal physical examination and a reactive serum quantitative nontreponemal test that is less than fourfold the maternal titer (possible congenital syphilis), further evaluation and treatment depend on the maternal treatment history and stage of infection (see [Fig. 144.3](#) and [Table 144.6](#)). Whether to perform a complete evaluation (lumbar puncture, radiographs of the long bones, and complete blood cell and platelet counts) on the infant depends on the maternal treatment history and planned treatment of the infant (see [Treatment](#)). If the mother did not receive any prior treatment for syphilis, or the treatment was inadequate, a complete evaluation must be performed and be normal if a single intramuscular dose of benzathine penicillin G therapy is administered. Although it is preferred to help establish a diagnosis of congenital syphilis, a complete evaluation is unnecessary if a full 10-day course of parenteral penicillin is provided because such therapy would treat for the possibility of congenital infection.^{13,93}

A full evaluation also is not needed if the infant's nontreponemal test is nonreactive and the physical examination is normal because it is unlikely to reveal any abnormalities that would require prolonged penicillin therapy.

The need to perform a lumbar puncture has been questioned because the yield of abnormal findings from examination of the CSF has been very low in some experiences and appreciable in others.^{10,42,120} A primary benefit of obtaining CSF studies from infants who are receiving a 10-day parenteral course of aqueous or procaine penicillin therapy is identification of infants for whom follow-up of abnormal CSF results should be done. Likewise, radiographs of long bones are abnormal in approximately 65% of infants with clinical findings of syphilis but only in a few asymptomatic infants. The finding of osteochondritis or periostitis in an infant born to a mother with reactive serologic tests for syphilis indicates congenital syphilis, and the infant requires a full course of penicillin therapy for highly probable disease. Such an infant is likely to have CNS infection, however, even in the absence of clinical signs of neurosyphilis, and close clinical and serologic follow-up would be indicated.⁹¹

After the neonatal period, children with syphilis should have a lumbar puncture performed for evaluation of the CSF to detect asymptomatic neurosyphilis. In addition, birth and maternal records should be reviewed to assess whether such children have acquired or congenital syphilis.²⁸ Children with acquired syphilis should be evaluated for the possibility of sexual abuse.⁷²

TREATMENT

T. pallidum is extremely sensitive to penicillin, as defined by experimental animal work. The minimal inhibitory concentration of penicillin is approximately 0.004 units/mL (or 0.0025 µg/mL). There is no evidence of increasing resistance to penicillin by the spirochetes, but such evidence would come only from the recognition of therapeutic failures. Effective treatment of syphilis must maintain a minimal inhibitory concentration of 0.03 units/mL of penicillin in serum (or CSF) for 7 to 10 days. Therapy is designed to achieve and maintain several times the necessary inhibiting levels and to avoid penicillin-free intervals during therapy. Penicillin remains the drug of first choice because of its established efficacy and minimal toxicity.²²

Acquired Syphilis

Early syphilis (i.e., primary, secondary, and early latent infection) is treated with benzathine penicillin G, 50,000 units/kg up to the adult dose of 2.4 million units IM in a single dose. Late latent syphilis requires benzathine penicillin G, 150,000 units/kg up to the adult dose of 7.2 million units, administered as 50,000 units/kg up to the adult dose of 2.4 million units at 1-week intervals for 3 weeks. When the duration of infection is unknown, the patient should be treated as for late latent disease.

All patients with syphilis should be tested for HIV infection at diagnosis, although HIV-infected individuals are managed in the same manner as HIV-negative patients. Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months. A CSF examination should be performed if (1) neurologic or ophthalmic signs or symptoms are present or develop, (2) the patient has tertiary syphilis, (3) a sustained (>2 weeks) fourfold increase or greater in titer is observed and reinfection unlikely, (4) an initially high titer ($\geq 1:32$) fails to decline at least fourfold within 12 to 24 months of therapy, or (5) signs or symptoms attributable to syphilis persist, recur, or develop following therapy. In such circumstances, patients with CSF abnormalities should be treated for neurosyphilis.²⁴ Benzathine penicillin does not produce inhibitory CSF levels of penicillin reliably.¹³⁹ Shorter acting penicillins must be employed for neurosyphilis. In evaluating a patient for neurosyphilis, a CSF specimen without contamination by peripheral blood is needed.⁶⁶

The recommended therapy for neurosyphilis is aqueous crystalline penicillin G, 18 to 24 million units/day, administered as 3 to 4 million units intravenously every 4 hours or continuous infusion for 10 to 14 days. An alternative regimen consists of procaine penicillin, 2.4 million units IM once daily, plus probenecid, 500 mg orally four times per day, for 10 to 14 days. Because these regimens are of shorter duration than is the regimen used for late latent syphilis, some experts recommend the additional administration of benzathine penicillin G, 2.4 million units IM once per week for up to 3 weeks after completion of the 10- to 14-day course. Older children with definite acquired syphilis and a normal neurologic and CSF examination may be treated with benzathine penicillin G, 50,000 units/kg IM to a maximal dose of 2.4 million units. Children with neurosyphilis should receive aqueous penicillin G, 200,000 to 300,000 units/kg per day intravenously administered as 50,000 units/kg every 4 to 6 hours for 10 days. Similar to the procedure with adults, an additional dose of benzathine penicillin G, 50,000 units/kg IM, may be given following the 10-day intravenous penicillin treatment.

The evaluation and treatment of early syphilis in HIV-infected individuals are the same as for individuals not infected with HIV except that they may be at increased risk for developing neurologic complications and have a higher risk for experiencing treatment failure. Close serologic follow-up of HIV-infected individuals is mandatory to detect treatment failure and the need for examination of CSF and retreatment.

Data to support the use of alternatives to penicillin in the treatment of syphilis are limited. Any history of penicillin allergy should be documented clearly, and, whenever possible, patients should receive skin testing, desensitization, and therapy with penicillin.²⁴ Doxycycline 100 mg orally twice daily and tetracycline 500 mg four times daily have been used for 14 days for treatment of early syphilis and 28 days for late latent infection and syphilis of unknown duration. Close serologic follow-up is mandatory. Neither of these therapies is recommended for children younger than 8 years. Ceftriaxone 100 mg/kg per day (maximum of 1 g daily) given either intravenously or IM for 10 to 14 days may be effective for treating early syphilis, but neither the optimal dose nor the duration of treatment has been defined.⁵⁹ Preliminary data also suggest that azithromycin as a single dose of 2 g may be effective in adults, but treatment failures have been described, as has emergence of resistance.²⁴ Because experience with these alternative antibiotics in HIV-infected individuals is limited, they should be used with caution.

Two to 12 hours after receiving treatment for syphilis, a variable proportion of patients develop an acute systemic (Jarisch-Herxheimer) reaction usually consisting of headache, malaise, fever ($\geq 38^\circ\text{C}$ [100.4°F]), and resolution within 1 day. The reaction is observed most frequently in the early stages of syphilis, probably represents a reaction to liberated

endotoxin,⁴⁸ and does not affect the course of recovery. In the later stages of syphilis, fewer than one in four patients develop the reaction. Most reactions in late syphilis clinically are insignificant, but an occasional reaction may produce damage to the CNS or cardiovascular system.

Syphilis in Pregnancy

Pregnant women with reactive serologic tests for syphilis should be considered infected unless an adequate treatment history is documented and sequential nontreponemal antibody titers have declined. They should receive the penicillin regimen appropriate for the stage of syphilis.^{24,150} For early syphilis, some experts recommend that an additional dose of benzathine penicillin G be provided 1 week after the initial dose. Management and treatment decisions may be guided further by the use of fetal ultrasonography. Evidence of fetal infection may require additional doses of benzathine penicillin G until resolution of fetal abnormalities has been achieved. The Jarisch-Herxheimer reaction may complicate treatment and result in preterm labor and fetal decelerations, although concern for its occurrence should not delay initiation of treatment.^{71,96} No alternative to penicillin is available; pregnant women who have a history of penicillin allergy should undergo skin testing, desensitization, and treatment with penicillin.¹⁵¹ Neither erythromycin nor azithromycin is recommended; infants have been born with congenital syphilis after maternal treatment with both agents. Any therapy other than penicillin is considered to be inadequate fetal therapy.^{41,109}

Women who are coinfecting with syphilis and HIV should receive treatment regimens corresponding to their stage of syphilis. The follow-up on treated HIV-infected women must be thorough and frequent.^{55,95}

Patients who received therapy for gonorrhea with ceftriaxone have a high rate of cure of preprimary syphilis, but failures have occurred, and efficacy in pregnancy is not well studied.⁵⁹ This regimen cannot be assumed to have provided adequate therapy for syphilis in pregnancy.

Congenital Syphilis

Infants With Proven or Highly Probable Disease

Infants who have findings on physical examination that are consistent with congenital syphilis, such as a serum quantitative nontreponemal serologic titer that is at least fourfold greater than the mother's titer or spirochetes visualized or detected by PCR in body fluids or lesions, should be treated with aqueous crystalline penicillin G, 50,000 units/kg/dose intravenously every 12 hours during the first 7 days of age and every 8 hours thereafter for 10 days, or with procaine penicillin G, 50,000 units/kg/dose administered IM in a single daily dose for 10 days (see Table 144.6).²⁴ Although the concentration of penicillin that is achieved in the CSF during procaine therapy is lower than the levels seen with intravenous penicillin treatment, the clinical significance is unclear.⁵ No treatment failures have been reported after procaine penicillin therapy. If more than 1 day of penicillin therapy is missed, the entire course should be restarted.

During a penicillin shortage in the United States, ceftriaxone was recommended as an alternative agent, although data are insufficient for its routine administration (see <http://www.cdc.gov/std/treatment/drugnotices/penicilling.htm>). When possible, a full 10-day course of penicillin is preferred even if ampicillin or another agent was provided initially for possible sepsis. Infants born to mothers coinfecting with syphilis and HIV do not require more intense or prolonged treatment for syphilis than is recommended for all infants.

Infants With a Normal Physical Examination and a Serum Quantitative Nontreponemal Serologic Titer the Same or Less Than Fourfold the Maternal Titer

Treatment decisions for "asymptomatic" infants are based on the maternal history of syphilis and past treatment. The following situations are associated with a high likelihood that the infant may be infected with *T. pallidum* and should receive treatment: (1) mother was not treated, was inadequately treated, or has no documentation of having received treatment¹¹³; (2) mother was treated with erythromycin or other nonpenicillin G regimen; or (3) mother received recommended treatment less than 4 weeks before delivery.¹⁴ If the infant's nontreponemal test is reactive, the infant should be evaluated with a complete blood cell

count and differential; platelet count; radiographs of long bones; and CSF analysis for VDRL test, cell count, and protein content (Fig. 144.4 and Table 144.6).²⁴ If the entire evaluation is normal and follow-up is certain, the infant may receive benzathine penicillin G, 50,000 units/kg as a single IM dose.

If any part of the evaluation is abnormal or not done, or follow-up is uncertain, treatment should consist of aqueous penicillin G or procaine penicillin G (see earlier discussion) for 10 days. If the infant's nontreponemal serum test is nonreactive, the evaluation may be omitted, but the infant should be treated with a single intramuscular dose of benzathine penicillin for the possibility of incubating syphilis. Some experts prefer that all infants born to mothers with untreated syphilis receive parenteral penicillin therapy for 10 days because even if the evaluation is normal, these infants are at increased risk for being infected with *T. pallidum*, especially if the mother has secondary syphilis at delivery.²⁴

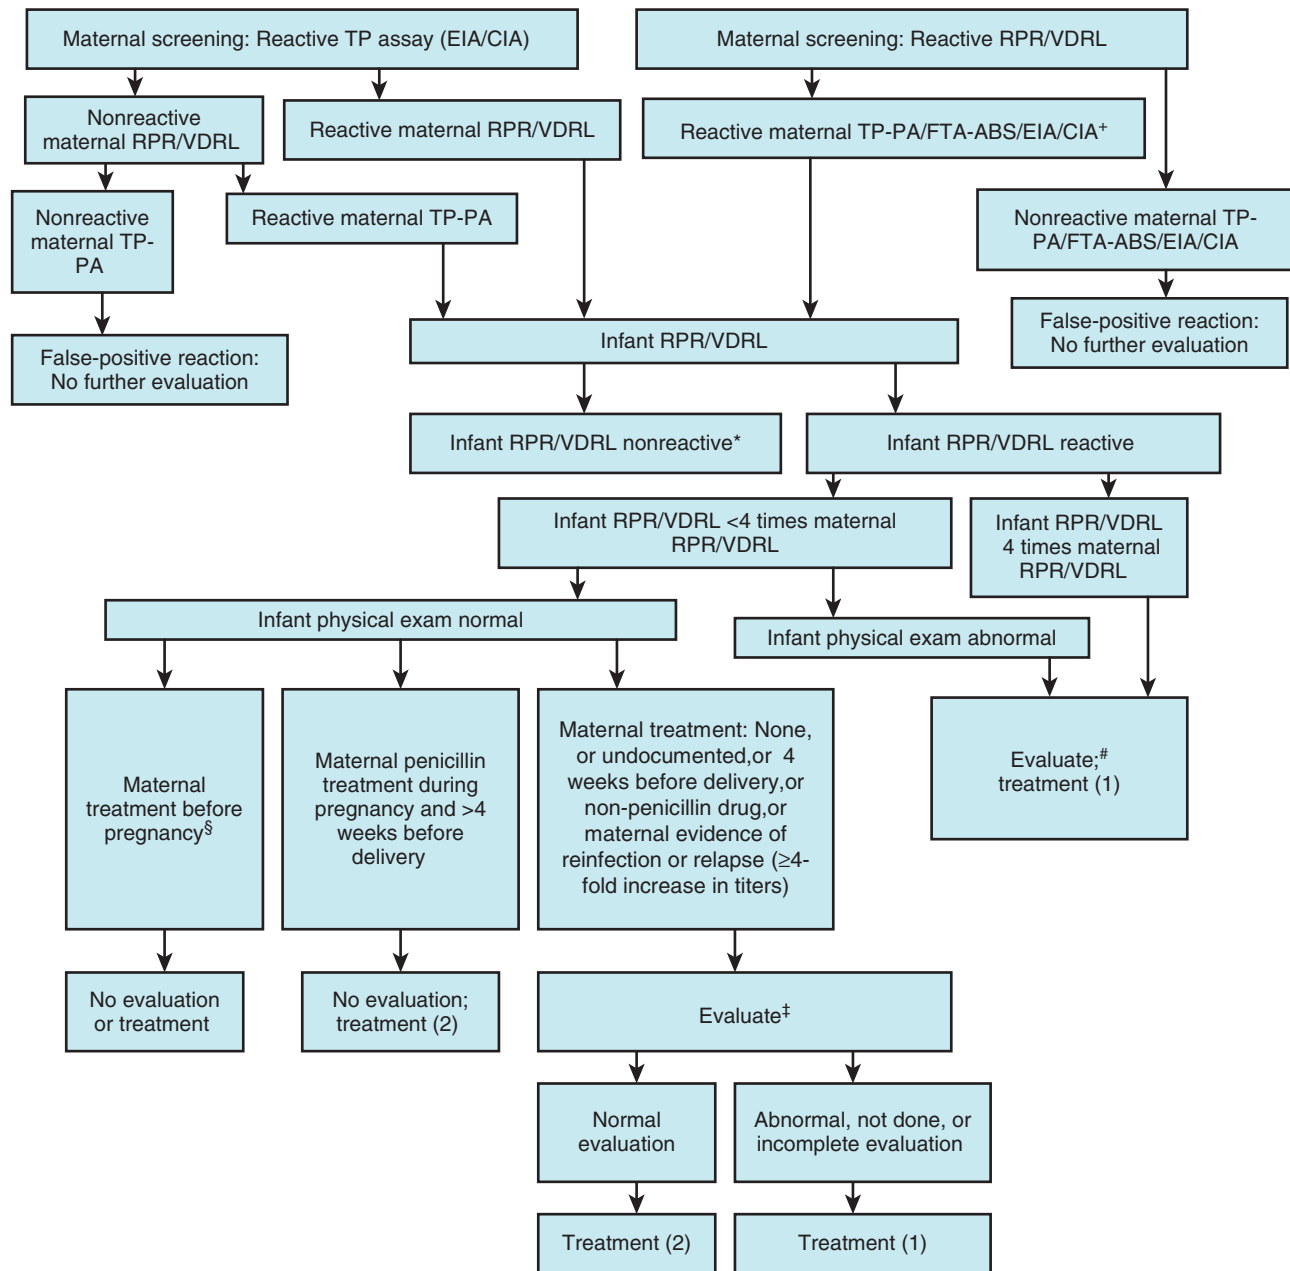

Some studies have reevaluated the efficacy of treatment regimens for asymptomatic infants who are born to mothers in whom the treatment for possible syphilis was suboptimal.^{105,110} Paryani and colleagues¹⁰⁵ randomly assigned 152 infants to receive either one injection of benzathine penicillin or a 10-day course of parenteral procaine penicillin. All study infants were asymptomatic on physical examination and had normal CSF evaluation, normal radiographic studies of long bones, and no visceral abnormalities. The results of both forms of therapy were excellent, with no treatment failures. This study indicates that single-dose therapy may have a high rate of success when an infant has negative studies and no symptoms.

Failure of a single administration of intramuscular benzathine penicillin G in three infants has been reported; however, the frequency seems to be low.^{10,155} None of the three infants who developed clinical signs of congenital syphilis several weeks after having received a single intramuscular dose of benzathine penicillin was fully evaluated for congenital syphilis at birth. The concern has been that infected but symptom-free infants may have CNS infection and fail therapy with benzathine penicillin because benzathine penicillin does not achieve treponemicidal concentrations in CSF.¹³⁹ Using rabbit inoculation, Michelow and colleagues⁹¹ showed that invasion of the CNS is an infrequent occurrence among these infants who have normal results on clinical, laboratory, and radiographic evaluations.

An infant does not require any evaluation in the following situations: (1) the mother was treated during the pregnancy, treatment was appropriate for the stage of infection, and treatment was administered more than 4 weeks before delivery; and (2) the mother has no evidence of reinfection or relapse. The CDC recommends, however, that these infants receive a single dose of benzathine penicillin G, 50,000 units/kg IM.^{69,24} Infection of the fetus may occur despite administration of appropriate maternal therapy during pregnancy; failure rates of maternal treatment for prevention of fetal infection have been reported to be 2% to 14% and are more common with maternal secondary syphilis.^{2,32,98,132} Treating the infant at birth may prevent the development of clinical disease if these infants were infected in utero. Some specialists would not treat the infant, however, but would provide close serologic follow-up only.

If the mother's treatment was adequate before pregnancy, and the mother's nontreponemal serologic titer remained low and stable during pregnancy and at delivery, no evaluation or treatment is recommended by the CDC. Some specialists would provide a single intramuscular dose of benzathine penicillin, however, if follow-up were uncertain for the remote possibility that the mother was reinfecting. These infants are at very low risk for having congenital syphilis; for the most part, these mothers are serofast.

After the neonatal period, all children who are diagnosed with congenital syphilis should be evaluated with a complete blood cell count and differential, platelet count, and examination of the CSF for VDRL, cell count, and protein. Other tests, such as auditory brainstem responses, long bone radiographs, and neuroimaging, should be performed as clinically indicated. These children and children with late congenital syphilis should be treated with 200,000 to 300,000 units/kg per day of aqueous crystalline penicillin G, given as 50,000 units/kg every 4 to 6 hours for a minimum of 10 to 14 days. However, if the infant or child

**TREATMENT:**

- (1) Aqueous penicillin G 50,000 U/kg IV q 12 hr (1 wk of age), q 8 hr (>1 wk), or procaine penicillin G 50,000 U/kg IM single daily dose, x 10 days
 (2) Benzathine penicillin G 50,000 U/kg IM x 1 dose

FIG. 144.4 Algorithm for evaluation and treatment of infants born to mothers with reactive serologic tests for syphilis. +, Test for HIV antibody. Infants of HIV-infected mothers do not require different evaluation or treatment. *If the mother has had no treatment, undocumented treatment, treatment ≤ 4 weeks before delivery, or evidence of reinfection or relapse (fourfold or higher increase in titers) and the infant's physical examination is normal, then treat infant with a single intramuscular injection of benzathine penicillin (50,000 U/kg). No additional evaluation is needed. §Women who maintain a VDRL titer $\leq 1:2$ (RPR $\leq 1:4$) beyond 1 year after successful treatment are considered serofast. #Evaluation consists of CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL. Other tests as clinically indicated: long-bone x-rays, neuroimaging, auditory brainstem response, eye examination, chest radiograph, liver function tests. ‡CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL; long-bone radiographs. Treatment regimens are as follows: (1) aqueous penicillin G 50,000 units/kg IV every 12 hours (≤ 1 week old) or every 8 hours (>1 week old) or procaine penicillin G 50,000 units/kg IM single daily dose x 10 days; (2) benzathine penicillin G 50,000 units/kg IM x 1 dose. CBC, Complete blood count; CIA, chemiluminescence; CSF, cerebrospinal fluid; EIA, enzyme immunoassay; RPR, rapid plasma reagin; TP, *Treponema pallidum*; TP-PA, *Treponema pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory.

has no clinical manifestations of congenital syphilis and the evaluation (including the CSF examination) is normal, treatment with up to 3 weekly doses of benzathine penicillin G, 50,000 U/kg IM can be considered. In addition, a single dose of benzathine penicillin G 50,000 units/kg IM up to the adult dose of 2.4 million units in a single dose can be considered after the 10-day course of IV aqueous penicillin to provide more comparable duration of treatment in those who have no clinical manifestations and normal CSF.

The Jarisch-Herxheimer reaction may complicate the treatment of congenital syphilis. It rarely is seen in newborns, although it occurs more commonly when syphilis is treated later in infancy. It is manifested usually by fever, but cardiovascular collapse and seizures also have been reported.

FOLLOW-UP EVALUATION

Box 144.5 summarizes recommendations concerning follow-up of infants after they have been treated for congenital syphilis and of seroreactive infants who were not treated because of the presumed adequacy of the management of the mother's serologic status.^{60,61,113} Infants born to mothers with syphilis should have serial quantitative nontreponemal tests performed until the test results show nonreactivity.^{56,118} Similarly, infants who are seronegative but whose mothers acquired syphilis late in gestation should be followed with serial testing after penicillin therapy is instituted.

Follow-up for infants who received appropriate penicillin therapy for possible syphilis can be incorporated into routine pediatric care at 2, 4, 6, 12, 15, and 24 months. These infants should show a fourfold decrease in nontreponemal serologic titers. In infants with congenital syphilis, nontreponemal serologic tests become nonreactive within 6 to 12 months after they have received appropriate treatment. Uninfected infants usually become seronegative by the time they reach 6 months of age.²⁷ Infants with persistently low, stable titers of nontreponemal tests beyond 1 year of age may require retreatment.

BOX 144.5 Recommended Follow-up of Infants Born to Mothers With Syphilis

1. Nontreponemal test (e.g., RPR):
 - a. *Treated infant*: Perform at 2, 4, 6, 12, 15, and 24 months old (or after therapy) until nonreactive. Nontreponemal test titer should decrease fourfold within 6 months after treatment and be nonreactive by 6 to 12 months. If test remains reactive ≥ 12 months after treatment, consider reevaluation and retreatment. If nontreponemal test titer increases fourfold, full reevaluation and retreatment for proven disease is required.
 - b. *Untreated infant*: Perform at 1, 2, 4, 6, 12, 15, and 24 months old (or after therapy) until nonreactive. Nontreponemal test titer should decrease fourfold within 6 months after treatment and be nonreactive by 6 months. If nontreponemal assay is reactive at 6 months, reevaluate child (including CSF examination) and treat. If nontreponemal test titer increases fourfold, full evaluation and treatment for proven disease are required.
2. Treponemal test (e.g., TP-PA): Perform at 12 months. If reactive, repeat at ages 18 and 24 months.^a
3. Abnormal CSF examination at diagnosis: Repeat CSF examination (VDRL, cell count, protein content) at age 6 months (or after therapy). If abnormal and no other explanation found, retreat infant.
4. Monitor yearly for neurologic, hearing, and ophthalmic disorders.
5. Monitor developmental status and assess school function.

^aApproximately 30% of infected children maintain a reactive treponemal test beyond age 18 months. This finding confirms the diagnosis of congenital syphilis. If child was not previously treated, treatment for proven congenital syphilis is mandatory. CSF, Cerebrospinal fluid; RPR, rapid plasma reagin; TP-PA, *Treponema pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory. Modified from Ikeda MK, Jensen HB. Evaluation and treatment of congenital syphilis. *J Pediatr*. 1990;117:843–852; and Rathbun KC. Congenital syphilis: a proposal for improved surveillance, diagnosis and treatment. *Sex Transm Dis*. 1983;10:102–107.

Untreated infants may benefit from having a nontreponemal test performed at 1 month of age. Untreated infants whose nontreponemal test remains reactive by the time they are 6 months old may need to be reevaluated clinically and treated. If the nontreponemal titer increases fourfold in any infant during follow-up, full evaluation and treatment are indicated. All infants and children should be evaluated thoroughly for the extent of disease if there is serologic evidence of failure of treatment or of recurrent disease. At a minimum, such evaluation should consist of CSF examination and complete blood cell count and platelet count. Other tests, such as long bone radiographs, liver function tests, hearing evaluation, and ophthalmologic evaluation, can be performed as clinically indicated.

A reactive treponemal test in infants who are 18 months or older when they have lost all maternal antibody confirms the diagnosis of congenital syphilis. A nonreactive treponemal test at that time indicates the lack of active and ongoing infection, but it does not exclude a previously infected child who was treated adequately in the neonatal period. Seroreversion of the treponemal test has been seen in some infants with treated congenital syphilis as documented by the detection of spirochetes in blood or CSF. However, if the child did not receive treatment previously and the treponemal test remains reactive at 18 months or older, a full evaluation and treatment are indicated.

Infants with abnormal CSF findings should have a repeat lumbar puncture performed 6 months after therapy. A reactive CSF VDRL test result or an abnormal protein content or cell count at that time is an indication for retreatment.

Adults and older children with primary or secondary syphilis should be examined clinically and serologically at least at 6 and 12 months after treatment. Failure of nontreponemal titers to decrease fourfold within 6 to 12 months of treatment indicates possible treatment failure. These individuals should be reevaluated for HIV infection, and consideration should be given to performance of a lumbar puncture for detection of unrecognized neurosyphilis and retreatment. For latent syphilis, subsequent follow-up with quantitative serology at 6, 12, and 24 months is recommended. Failure of a fourfold decrease in initially elevated nontreponemal serologic titers (1:32) within 12 to 24 months of therapy is an indication for examination of CSF and retreatment. Retreatment for syphilis also is recommended when clinical signs or symptoms persist or recur, or if there is a sustained fourfold increase in titer of a nontreponemal serologic test. Patients with neurosyphilis require examinations and repeat CSF examinations every 6 months until the CSF results are normal. After 2 years of follow-up, a reactive CSF VDRL test or abnormal CSF index that persists and cannot be attributed to other ongoing illness requires retreatment for possible neurosyphilis.

In most patients receiving appropriate therapy during the primary or secondary stages, active disease is arrested totally and permanently. Persistent seroreactivity as measured by a treponemal test may be avoided if treatment is given during the preprimary stage, but seldom thereafter. Nonetheless, progression to tertiary disease seldom, if ever, occurs. Similarly, therapy administered during early or late latent syphilis averts the development of symptomatic tertiary disease. Antimicrobial therapy for symptomatic neurosyphilis, optic neuritis, and cardiovascular syphilis may not be followed by significant clinical improvement, and established damage to vital organs may fail to resolve.

PREVENTION

Methods to control the spread of syphilis have relied extensively on treatment of case contacts. Individuals with active syphilis are interviewed to identify all sexual contacts that may have occurred at (1) 3 months plus duration of symptoms for primary syphilis, (2) 6 months plus duration of symptoms for secondary syphilis, and (3) 1 year for early latent syphilis. The contacts are examined, tested serologically, and treated appropriately even if they are seronegative. Advantage is taken of the long incubation period of syphilis by preventing disease in contacts before they can transmit infection.

Adverse outcomes of pregnancy and congenital infection can be prevented effectively by performing routine prenatal serologic screening and providing penicillin treatment to infected women and their sexual

partners.^{138,146} All pregnant women should have a serologic test for syphilis at the first prenatal visit. For communities and populations in which the prevalence of syphilis is high or for patients at increased risk for contracting disease, serologic testing should be performed at 28 to 32 weeks' gestation and at delivery because some women may acquire syphilis during pregnancy.⁴ When epidemiologic, clinical, or serologic evidence of infection is present, or the diagnosis of active infection cannot be excluded, treatment should be instituted.

For years, nontreponemal antibody testing has been recommended for antepartum syphilis screening. Recently, treponemal antibody testing is being used increasingly by many laboratories as a cost-cutting measure for screening pregnant women (reverse sequence screening). If a treponemal EIA or CIA test is used for antepartum syphilis screening and is positive, a quantitative nontreponemal test (RPR or VDRL) should then be performed. If the nontreponemal test is reactive, then a diagnosis of past or present syphilis is made and the management of the mother and infant should be as discussed previously. However, if the nontreponemal test is negative, then the results are considered discrepant and a second treponemal test (TP-PA preferred) should be performed, preferably on the same specimen. If the second treponemal test is positive, current or past syphilis infection is confirmed. For women with a history of adequately treated syphilis, no further treatment is necessary. Women without a history of treatment should be staged and treated accordingly with a recommended penicillin regimen. If the second treponemal test is negative, the positive EIA/CIA is more likely to represent a false-positive test result in low-risk women with no history of treated syphilis.¹⁰⁴

Serologic screening tests should be performed on maternal serum and not on the infant's serum or umbilical cord blood.¹¹⁶ An infant's nontreponemal serologic titer usually is one to two dilutions less than that of the mother's titer; an infant may have a nonreactive serologic test for syphilis when the maternal titer is of low dilution. Some of these infants, especially infants born to mothers with no prior treatment for syphilis, require treatment for prevention of late-onset disease. They would be missed if only infant screening were performed.

Limitations of current screening practices also exist. A false-negative nontreponemal test can occur from a prozone phenomenon. Also, a negative maternal nontreponemal test at delivery does not exclude incubating syphilis or even primary syphilis if nontreponemal and treponemal antibodies have not yet reached detectable concentrations.^{38,125} Infants born to such mothers may be infected and develop clinical disease in the ensuing 3 to 14 weeks. Repeat screening of mothers who reside in areas with a high prevalence of syphilis or engage in high-risk behaviors may be advisable at the first postpartum visit.

It is a policy statement of the CDC that no infant should leave the hospital without the serologic status of the infant's mother having been documented at least once during pregnancy and preferably again at delivery.^{24,86} In this era of early and very early discharge from the hospital after deliveries, fulfilling the policy goal may require careful planning and advocacy by the clinician.

All syphilis cases must be reported to the local public health department. This practice allows for contact investigation, appropriate follow-up, and identification of core environments and populations in which the greatest transmission of syphilis is occurring in a particular community. Despite great progress in recent years, the prevention, control, and even elimination of endemic syphilis in the United States remain an elusive goal in public health policy and on a global scale in countries where resources may be limited and the practicalities of serologic screening and treatment in prenatal care settings are challenging. However, as discussed in the Epidemiology section, the WHO initiative to achieve global elimination of congenital syphilis is making progress. Linking to a dual integrated strategy of eliminating mother-to-child HIV transmission affords the opportunity of synergistic benefits. The median proportion of pregnant women receiving at least one antenatal care visit is now 90% in 58 reporting countries, and there have been notable successes in declaring some countries free of mother-to-child transmission of syphilis.⁶⁸

Nonvenereal Treponematoses

David C. Hilmers

Pinta, yaws, and endemic syphilis (bejel) are the three chronic granulomatous diseases that constitute the pathogenic nonvenereal treponematoses of humans. These diseases are caused by morphologically indistinguishable treponemes found almost exclusively in underdeveloped areas of the tropics and bordering arid regions. The pathogenic treponemes have been given subspecies designations as follows: syphilis, *Treponema pallidum* subsp. *pallidum* (*T. pallidum*); yaws, *T. pallidum* subsp. *pertenue* (*T. pertenue*); and endemic syphilis, *T. pallidum* subsp.

endemicum (*T. pallidum*). The designation for the causative agent of pinta remains *Treponema carateum* (Table 145.1).⁴⁰

Although neither sexually nor congenitally acquired, agents responsible for the nonvenereal treponematoses are transmitted person to person by means of skin or mucous membrane contact. Close contact with children or young adults, traumatized areas of skin, lack of clothing, and poor personal hygiene are important factors in the transmission of these diseases. All three nonvenereal treponematoses are potentially

TABLE 145.1 Comparison of the Treponematoses

	Syphilis	Yaws	Endemic Syphilis	Pinta
Organism	<i>T. pallidum</i> subsp. <i>pallidum</i>	<i>T. pallidum</i> subsp. <i>pertenue</i>	<i>T. pallidum</i> subsp. <i>endemicum</i>	<i>T. carateum</i>
Distribution	Worldwide	Tropics, Africa, Asia, Pacific	Arid areas of Africa, Arabia	Tropical Central, South America
Peak ages affected	All ages	1–12 y	<15 y	15–20 y
Route of entry	Mucous membranes	Skin	Oral mucosa, fomites	Skin
Incubation period	2–10 wk	3–9 wk	3 wk	2–3 wk
Experimental hosts	Rabbit, primate, guinea pig, hamster	Rabbit, hamster	Rabbit, hamster	Primate only
Sexual transmission	Yes	No	No	No
Congenital transmission	Yes	No	No	No
Skin infection	Yes	Yes	Yes	Yes
Bone involvement	5–10%	20–40%	20–40%	0
Neurologic involvement	Yes	No	Rare	No
Cardiologic involvement	Yes	No	Rare	No

debilitating diseases that have enormous social and economic implications within endemic areas.²⁵ The worldwide prevalence was reduced considerably by means of seroepidemiologic and mass treatment campaigns sponsored by the World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF) in the 1950s and 1960s. A new campaign for eradication of yaws has recently been formulated by the WHO (the Morges strategy) in which single-dose azithromycin to treat entire communities is used.⁵ This strategy also includes follow-up assessment of efficacy using serologic surveys at 6-month intervals. The goal is to eradicate at least one of these diseases, yaws, by the year 2020. There are no specific plans for eradication of endemic syphilis and pinta because more epidemiologic and molecular data are required before an eradication strategy can be promulgated for these less well-characterized diseases. As for now, all three remain public health problems in areas of the world where sporadic outbreaks continue to occur.⁴⁰

Since the termination of the mass treatment campaigns in the 1960s, lack of attention to these diseases and diversion of resources to other public health problems, such as human immunodeficiency virus, malaria, and tuberculosis, led to a resurgence in the nonvenereal treponematoses in some parts of the world. Because of a lack of vigilance and awareness of these diseases, they probably are underreported. Data reported by WHO in 1997 estimated that there were more than 2.5 million cases worldwide.¹⁸ The potential effectiveness of a determined treatment and surveillance program was demonstrated in a region of northern Ecuador where no new cases of yaws were reported from 1993 to 1998.² Before the inception of this program there was a prevalence of clinical cases of 16.5% in the area's population. A focused effort in India has also been successful, and no new cases have been reported since 2004.⁴ There is great hope that a determined and organized campaign using a single dose of azithromycin can successfully eliminate these diseases.⁴⁶

The history, development, and global spread of treponemal diseases have been the subject of widespread debate.³⁶ Because the primary reservoirs for these organisms are humans, their history is intertwined within the economic, cultural, and social framework of humanity. One theory postulates that all treponemal diseases originated from pinta or yaws, first found in Central Africa. This view states that treponemes spread widely from there, and the various disease processes that we know today are a result of mutations caused by the adaptation of the organisms to environmental and development changes in their hosts. Supporters of the pre-Columbian existence of syphilis in Europe point to radiocarbon dating of skeletons in 14th-century England that appear to bear the stigmata of syphilis. Critics of this evidence point to possible inaccuracies in methods and lack of peer review.^{3,66} The Columbian theory suggests that treponemes began as nonvenereal pathogens in Africa that spread to the Americas via Asia thousands of years ago while mutating into endemic syphilis as they crossed Africa and Asia. In North America, they developed into the venereally transmitted form of disease caused by *T. pallidum* that we know today as syphilis. Syphilis was

carried to Europe by Columbus and his men on his return voyage from the Americas. Supporters of this theory point to skeletal evidence of syphilis found in the Dominican Republic before the arrival of Columbus on the island and to evidence of nonvenereal treponemal infections, but not syphilis, in England during the same period.⁷³ More recent investigations in Guyana found an isolated tribe with treponemal infections that had characteristics of both yaws and syphilis. Phylogenetic analysis of this strain lends support to the Columbian theory of the origin of syphilis and the Old World roots of the nonvenereal species.^{30,74,75}

On morphologic examination, the treponemes are thin, tightly coiled organisms that do not stain or stain poorly with the usual aniline dyes. They contain 4 to 14 spirals and are actively motile by virtue of periplasmic flagella. The organisms are quite fragile and sensitive to drying, atmospheric oxygen, and temperatures greater than 35°C. The organisms can be stored in either 15% glycerol at –70°C or liquid nitrogen and still retain their virulence for long periods. Although limited multiplication of *T. pallidum* subsp. *pallidum* has been achieved in a tissue-culture system,¹⁹ it has not been accomplished as yet with the nonvenereal pathogenic treponemes. No human pathogenic treponemes have been cultured in or on artificial media. Because they measure 10 to 13 µm in length but only 0.15 µm in width, they are below the resolution of light microscopy and must be identified by darkfield microscopy in infected skin or mucous membrane lesions.

Sequencing of the yaws and endemic syphilis genomes has identified targets for molecular diagnostics that can differentiate venereal syphilis from yaws and bejel.^{11,64} For example, yaws and syphilis treponemes have been shown to differ by less than 0.2% of the genome sequence.¹⁰ It has also been shown that there is heterogeneity within strains at certain gene sites.⁹ Clinical and epidemiologic features of each disease state from which the treponeme is recovered constitute the primary method of differentiation. Although not practical, further differentiation is based on the response of animal models to experimental infection.^{29,33,54,60,61} Each of the pathogenic treponemes stimulates cross-reactive antibodies assayed in the serologic diagnosis of the human diseases by nontreponemal and treponemal tests. Various degrees of homologous resistance and cross-immunity exist after infection occurs with any of these spirochetes.^{29,31,37,41,42,60,68} Rabbit models have shown complete immunity against reinfection with homologous pathogens but only incomplete or nonexistent protection against other subspecies.⁶⁷ No specific antigenic differentiation has been found among species to explain these findings. Despite differences in methods of transmission, clinical disease, geographic distribution, and rare reports of resistant cases, all human treponemes remain sensitive to penicillin.^{7,18}

PINTA

Pinta (mal del pinto, carate, enfermedad azul) is a chronic, contagious, nonvenereally transmitted treponemal disease that normally is the mildest of these disorders. Although it affects primarily patients in the first 2

decades of life, it can affect children and adults of all age groups, producing dyschromic skin lesions without pathogenic involvement of deeper organ structures. Pinta is not a fatal disease, but a disfiguring one, which results in social ostracism and an inability to adjust to an urban society.

Biology and Immunology

Pinta is caused by *T. carateum*. The organism is characterized primarily by its isolation from patients with clinically apparent pinta and by its lack of pathogenicity in small laboratory animals. Only chimpanzees have been shown to be susceptible to experimental infection.^{34,35} Human studies by Medina⁴² suggest that *T. carateum* induces significant protection against homologous reinfection and cross-immunity against the treponemes of yaws and syphilis; however, these two subspecies of *T. pallidum* fail to confer cross-protection against *T. carateum*.⁴²

Epidemiology

Pinta is found primarily in tropical Central and South America among underprivileged Indians and in the Caribbean. It occurs in major river basins of Mexico, Venezuela, Colombia, Brazil, Peru, and Ecuador. Cases also have been reported in Argentina, Chile, Haiti, Guatemala, Dominican Republic, Honduras, Nicaragua, and Bolivia. Pinta rarely occurs at higher elevations in the mountain regions of these countries. In the early 1920s, approximately 500,000 cases occurred throughout Latin America; however, as a result of seroepidemiologic and mass treatment campaigns, few cases, if any, are being reported today. The possibility of underreporting exists because a 20% clinical prevalence was reported in 1982 in a village in Panama.⁵² A case of pinta in Austria in a visitor from Cuba was reported in 1999.⁷³

The disease is found where poor hygienic and crowded conditions exist. Although endemic areas basically are rural, tribal tradition allows very close contact among its members to occur. These tropical societies, with their absence of shoes and clothes, continually subject exposed skin to trauma and to contact with infectious lesions. Transmission of *T. carateum* occurs primarily by intimate skin-to-skin contact; a break in the skin is required for invasion of the treponeme. Pinta is not acquired congenitally or by blood transfusion. Transmission of the disease by insect vectors has been proposed but not proved⁴²; insects probably initiate disease by producing the necessary breaks in the skin.¹⁶ Pinta is distributed equally between males and females and among all races in endemic areas. It is acquired primarily by individuals aged 15 to 20 years,⁵³ frequently spreading to family members because of crowded living conditions.

Pathogenesis and Pathology

T. carateum penetrates skin through breaks in the epidermis, with resultant damage restricted to the dermal and epidermal tissues. The organisms multiply in these layers, eliciting cellular proliferation and plasma cell, lymphocyte, and Langerhans cell infiltration. The resulting primary lesions (one to three) may appear on any area of exposed skin but usually occur on the legs, the dorsum of the feet, the forearms, or the back of the hands.⁵³ A lesion enlarges as a result of continual progression and direct extension or by coalescence with adjacent primary lesions; occasionally, regional lymphadenopathy develops. Secondary lesions, known as *pintids*, may arise years later from treponemal dissemination and exhibit a cellular proliferation and infiltration similar to that of the primary lesion. In contrast to venereal syphilis, blood vessels remain intact and do not show proliferation. The dyschromic or multicolored nature (brown, slate blue, black, or gray) of the primary and secondary lesions is more characteristic of older than of younger lesions, in which pigmentary changes usually are minimal. The variously pigmented older lesions may show hyperkeratosis or parakeratosis. Large numbers of treponemes can be found throughout the dermis and epidermis in the highly contagious primary and secondary lesions.

Late pinta is characterized by pigmentary changes, from dyschromic treponeme-containing lesions to achromic treponeme-free lesions. This depigmentation process occurs at different rates even within the same lesion, which gives rise to different degrees of hypochromia and atrophy around dyschromic and achromic lesions.⁵³ A concomitant paucity of hair follicles and sebaceous glands may occur.¹⁵

Clinical Manifestations

Pinta is characterized by a continuing production of early infectious lesions from either direct extension or dissemination and by the concomitant presence of lesions in various stages of dyschromia and achromia. The lesions are not well delineated, often merge, and may be accompanied by regional lymphadenopathy. Primary, secondary, and tertiary stages may or may not occur simultaneously.

The early stage of pinta includes the initial lesions, occasional regional lymphadenopathy, and secondary lesions resulting from dissemination of treponemes. A primary lesion (not always evident) develops after an incubation period of 3 days to 2 months, usually 2 to 3 weeks. The primary lesion begins as one or more small erythematous papules that may appear scaly and indurated. The papules progressively enlarge over 1 to 3 months, often coalescing, becoming pigmented, more erythematous, and scaly while developing heaped-up margins. Occasionally, an accompanying regional lymphadenopathy is present. The lesion may disappear in several months or may continue to enlarge for several years, forming larger psoriasiform plaques that coalesce further.

The primary lesions of pinta generally overlap development of the secondary lesions or *pintids*, which appear months to years after infection occurs. During this stage, dissemination ensues and almost any area of the skin can be involved. The lesions occur typically on exposed areas of skin and are variously pigmented. The degree of pigmentation is related to the state of development of the lesion, the age of the lesion, the degree of exposure to sun, and the host's natural pigmentation. *Pintids* begin as small, scaly papules that gradually enlarge and coalesce. Several colors may exist within the same lesion. Initially, *pintids* usually are red to violaceous; later, they become slate blue, gray, or black as a result of photosensitization. Lesions on the legs typically are yellowish brown or dark brown.

The late stage of pinta is characterized by the development of depigmented lesions. Achromia usually begins several years after the onset of the disease but may appear 3 months after onset. Areas of depigmentation spread slowly, leaving large achromic lesions, reminiscent of vitiligo, as the end result. Early achromia tends to be asymmetric, whereas later depigmented lesions are symmetric. Characteristic of the Cuban form of pinta is the development of hyperkeratosis of the palms and soles. Many chronic dermatologic entities characterized by scaly, psoriasiform lesions or by dyschromia or depigmentation can be confused with pinta in endemic areas. Maculopapulosquamous diseases, including psoriasis, parapsoriasis, and lichen planus, and dyschromic dermatologic diseases such as vitiligo, ochronosis, and argyria must be taken into consideration.^{17,62}

Prognosis

Pinta is not a fatal disease; it produces changes related only to the skin. There is no involvement of the central nervous system, the cardiovascular system, or other internal organs. If the disease is not treated, the patient frequently develops large achromic cutaneous blemishes. The major resulting problem is one of social ostracism from the community. Infected individuals are removed from the urban society and find refuge in the rural areas. This isolation separates the patient farther from the principal sources of medical therapy.¹⁶

YAWS

Yaws (frambesia, pian, buba, bouba) is a communicable, nonvenereally transmitted treponematoses of the tropical zones. The disease is characterized by its early acquisition (usually before puberty) and its chronic, relapsing pattern of early benign lesions separated by periods of latency that terminate with late destructive lesions of skin, bones, and cartilaginous tissues. A very prevalent disease in the early part of the 20th century, yaws was estimated to have affected more than 50 million people. Although seroepidemiologic and mass treatment campaigns sponsored by WHO and UNICEF have reduced its overall prevalence dramatically, endemic areas of concern continue to exist.^{4,23,47,61,68} Data showing the efficacy of single-dose azithromycin at 30 mg/kg gives hope of eradicating the disease with a goal of the year 2020.⁴⁶

Biology and Immunology

T. pallidum subsp. *pertenue*, the etiologic agent of yaws, is morphologically identical to other pathogenic treponemes. The presence of infection with either yaws or syphilis strains was previously distinguishable only by epidemiologic and clinical means but now is possible by molecular probes.¹¹ The genomes of three strains of *T. pallidum* subsp. *pertenue* were completely sequenced and compared with four strains of *T. pallidum* in an attempt to find differences between the genomic structures of syphilis and yaws. The two genomes were found to have a 99.8% concordance. This is important in differentiating between childhood congenital syphilis and yaws, a distinction that can be clinically problematic.^{9,10}

Although not clinically useful, animal models can be used to distinguish between syphilis and yaws. Rabbits and hamsters have been infected experimentally by both diseases, with resultant lymphadenopathy and visible lesions. Characteristic differences in the distribution, form, and number of lesions can be used to distinguish the identity of the infectious agent. On the basis of human and experimental studies, the organism stimulates a significant degree of homologous resistance to reinfection and superinfection and cross-immunity to *T. pallidum* subsp. *pallidum* and *endemicum*.^{29,33,60,67}

Epidemiology

Yaws is a disease of tropical countries found primarily among rural populations. It exists in the warm, moist, endemic areas of rural Africa, Southeast Asia, the Caribbean, South America, the Pacific, and central and southern Africa. As indicated, seroepidemiologic and mass treatment campaigns have resulted in a significant reduction in prevalence of the disease in most of these areas. The failure of many countries to integrate active control measures into the functions of local health services has led, however, to a gradual buildup and extension of reservoirs of yaws, with the emergence of significant numbers of new, active cases since 1974 in Ghana, Togo, Benin, Indonesia, Papua New Guinea, and the Ivory Coast.⁴ In a WHO survey in the Central African Republic, Congo, and Gabon, clinical yaws was detected in more than 20% of the Pygmy population and reactive serologic tests were obtained in 80%. Health care workers in the periurban settlements of Port Moresby, Papua New Guinea identified 494 cases between April 2000 and September 2001. A 2001 survey in the Solomon Islands showed that yaws was the sixth leading cause of morbidity and that the prevalence was 4106 cases per 100,000 population.⁶⁵ In Lihir Island in Papua New Guinea, the prevalence of active yaws was found to be 2.4% and that of latent yaws in children was 18.3% before treatment.⁴⁶ In Latin America, cases still occur in Brazil, Colombia, Haiti, Venezuela, and Suriname.^{17,43} Intense surveillance and eradication efforts in India, however, appear to have been successful, with no new cases reported since 2004.⁴

Poor hygiene, close crowding among children (especially in sleeping areas), and lack of protective clothing facilitate transmission of the disease by direct skin-to-skin contact, whereby *T. pallidum* subsp. *pertenue* enters traumatized exposed areas from an infected lesion. The usual portals of entry are the lower extremities, head, face, and mouth. The presence of treponemal antibodies and the isolation of treponemes (most probably *T. pallidum* subsp. *pertenue* from West African monkeys)^{8,20} suggest that primates in this area may act as a reservoir for spread of the disease.

Yaws usually is acquired before puberty and is most prevalent among children. Because such a large percentage of the population contracts the disease in infancy, young children represent the primary reservoir. Older children and adults generally are not infectious; therefore, congenital and sexual transmission does not occur. Boys and girls are affected equally.

Pathogenesis and Pathology

T. pallidum subsp. *pertenue* enters the host through abraded skin, most frequently below the knees. The organisms multiply locally and in the regional lymph nodes. Epithelial hyperplasia and plasma cell, lymphocytic, and macrophage infiltration are elicited. The end result is the formation of a primary lesion and lymphadenopathy containing numerous treponemes. Shortly after their introduction into the host, organisms

are carried to skin, bone, and cartilage through the circulation. Disseminated treponemes in these tissues multiply, eliciting a chronic inflammatory response similar to that seen in the primary lesion. They produce distant papillomas, lymphadenopathy, hyperkeratosis, and bone involvement that develop without interruption until they are reversed by either immune mechanisms or treatment. In contrast to those associated with venereal syphilis, vascular changes are discrete or do not occur in cutaneous yaws.⁷¹

Untreated primary and secondary cutaneous lesions generally heal with only minimal scarring, unless they are complicated by secondary bacterial infection. The healing process and maintenance of latency seem to involve humoral and cellular mechanisms of immunity.⁵⁹ Relapses may occur during latency and, together with late disease, may be caused by a breakdown in the immune state, the development of antigenic variation by the treponeme, or both.

The late gummatous lesions presumably are caused by a hypersensitivity-induced mechanism similar to that postulated for the syphilitic gumma. Bone changes in late stages of yaws most often involve the long bones and manifest as hypertrophic periostitis, gummatous periostitis, osteitis, and nodular or generalized osteomyelitis.²⁶ Juxtaarticular nodules occur near major joints and are characterized as nonspecific granulomas.¹⁴

Clinical Manifestations

Yaws is a chronic, debilitating disease characterized by early infectious lesions; periods of latency and relapse; and late destructive lesions of cutaneous, subcutaneous, cartilaginous, and bony tissue. After an incubation period of 9 to 90 days (usually about 3 weeks), the primary lesion forms at the site of inoculation and is accompanied by regional lymphadenopathy. The lesion typically appears as a raised papule on the lower extremity that enlarges to become a hyperkeratotic papilloma measuring 2 to 5 cm in diameter, referred to as a *mother yaw*. It undergoes shallow ulceration and persists a few months to 3 years, at which time healing occurs with a resultant hypopigmented scar and surrounding dark margins.¹⁴

Before healing of the mother yaw or weeks to months thereafter, crops of secondary, generalized, nondestructive papular lesions appear together with lymphadenopathy and malaise. These lesions tend to form near areas with mucous membranes, such as the nose and mouth, and may resemble condylomata lata. Some papules fade, whereas others enlarge to become papillomatous lesions referred to as *satellite secondaries* or *daughter yaws*. The multiple papillomas are circular, raised, red-yellow lesions with a granular, lobulated, and verrucous surface. They contain numerous treponemes, usually measure 1 to 3 cm in diameter, and produce a yellow discharge that dries to form a black scab. Hyperkeratotic involvement of the palms and soles occurs commonly. Painful fissuring of the soles may cause the patient to walk on the sides of the feet, producing the characteristic gait of “crab” yaws. Bone pain may be severe, and nondestructive long bone lesions, including periostitis, osteitis, and osteomyelitis, may occur.^{14,26}

Untreated secondary lesions may persist for longer than 6 months, at which time, owing to the development of host immune mechanisms, they usually heal without scars or residual defects, unless ulceration caused by secondary bacterial infection occurs. During the dry season, early yaws lesions often are atypical, tending to be macular and fewer in number; papillomas, which are small, scanty, dry, flat, and grayish in appearance and of short duration (about 1 month), are confined mainly to the hidden, protected, moist skinfolds.^{49,53,69}

Despite healing, some treponemes evade the immune process and persist in the affected tissues (latency). Latency frequently is interrupted by relapses, which tend to occur several times over a 3- to 5-year period. Fewer lesions are produced with each relapse, and they tend to be localized to the periaxillary, perianal, or circumoral area. On cessation of the relapses and usually after a latent period of 3 to 10 years, tertiary lesions occur in 10% of patients; the latent state persists in the remaining patients for their lifetime.⁵³

The tertiary lesions characteristically are solitary and destructive; they involve skin, subcutaneous tissue, bone, or cartilage and most commonly occur after the onset of puberty. Painful hyperkeratosis of the palms and soles similar to that seen in early yaws frequently occurs. Other lesions develop as ulcerating, subcutaneous nodules and may

heal spontaneously to form scars or extend widely from their margins. The scarring results in depigmentation and sometimes contractions. Bone deformities of late-stage yaws include chronic hypertrophic periostitis, osteitis, gummatous periostitis, and osteomyelitis, each of which may ulcerate through the skin. Gangosa, or rhinopharyngitis mutilans, the destructive gummatous ulceration of the skin and bones of the central face, and juxtaarticular nodules, ganglions of tendon sheaths, and saber tibiae also may occur as manifestations of the late stages of the disease.²⁷ Gondou, a disfiguring hypertrophic osteitis of the frontal processes of the maxillae, previously reported among western Africans with yaws, seems to have disappeared.³⁸ Other diseases that must be differentiated from the skin lesions of yaws include vitamin deficiencies, early stages of leprosy, venereal syphilis, tinea versicolor, molluscum contagiosum, scabies, lichen planus, plantar warts, tungiasis, psoriasis, and cutaneous leishmaniasis. Sickle cell disease, tuberculosis, and bacterial osteomyelitis may produce clinical manifestations that mimic the osseous lesions of yaws.²⁸

Prognosis

Yaws is not a benign disease. If left untreated, it can produce destructive, disfiguring lesions of the face, feet, and hands and painful and disabling lesions of the fingers and long bones. Ulcers near joints may result in crippling contractures. Secondary bacterial infection of ulcers and of protruding bone lesions can result in further permanent damage to skin and bone tissues. Pathologic fractures generally do not occur.

ENDEMIC SYPHILIS

Endemic syphilis (bejel, njovera, siti, dichuchwa) is a chronic, nonvenereally transmitted disease of prepubescent children. It occurs in the warm, dry, arid regions of the world⁵³; lesions are confined to the skin, bone, and cartilage.⁵³ The disease, known to exist for centuries in Africa, has been recorded in epidemic proportions in areas where conditions among children allow transmission. As with yaws, although seroepidemiologic and mass treatment campaigns have reduced its overall prevalence drastically,⁷⁰ endemic areas of concern continue to exist and include the region bordering the southern Sahara Desert, Botswana, and the Arabian Peninsula.^{50,53,72}

Biology and Immunology

T. pallidum subsp. *endemicum*, the etiologic agent of endemic syphilis, morphologically is identical to the other pathogenic treponemes. *T. pallidum* subsp. *endemicum* exhibits similarity to syphilis and yaws by producing visible lesions and generalized lymphadenopathy in rabbits and hamsters experimentally infected by the intratesticular and intradermal routes.^{29,61} The degree of induration of lesions, distribution and number of lesions, and characteristic lymphadenopathy can be used to differentiate among the species. On the basis of experimental studies in inbred hamsters, *T. pallidum* subsp. *endemicum* stimulates a high degree of homologous resistance to reinfection and cross-immunity to *T. pallidum* subsp. *pallidum* and *T. pallidum* subsp. *pertenue*.^{61,67} The genome of the treponeme has been sequenced and was found to be very similar to yaws. However, it was also found to have some loci previously only seen in venereal syphilis.⁶⁴

Epidemiology

Endemic syphilis continues to persist in the warm, drier desert areas bordering the tropical belt. It is prevalent primarily among the seminomadic rural populations in the Arabian peninsula and along the southern border of the Sahara Desert in Africa known as the Sahel region^{50,53}; a significant resurgence occurred in Mali, Mauritania, Niger, and the upper Volta during the 1970s.⁴⁷ More than 1000 cases were reported in Senegal in 1980.⁴³ Although scattered endemic foci did exist in central Asia, Australia, Bosnia, and India, they have been virtually eliminated from these areas by mass treatment campaigns.^{50,53}

As with pinta and yaws, endemic syphilis propagates under conditions of poor hygiene, crowding, and wearing of little or no clothing. Transmission by oral mucous membranes is favored through contaminated objects, such as drinking vessels and kitchen utensils, and through contact with saliva-contaminated fingers and mouth-to-mouth contact.^{13,18,32} Fomites

are thought to play a role. Transmission may occur through direct contact of the oral lesion to skin.⁵³ Occasionally, a previously uninfected nursing mother develops a primary lesion on or near the nipple after the transfer of treponemes from her infected infant.^{23,72} Congenital transmission does not seem to occur. Recent analysis of pre-Columbian European skeletons found no endemic syphilis despite significant contact with cases during combat in the Crusades. The conclusions drawn from this analysis are that adults are not susceptible to transmission from other adults and furthermore that adults cannot transmit endemic syphilis.⁵⁷ The role of insect vectors, such as flies, has been suggested, but it may be caused by creating a portal of entry by breaks in the skin after itching. Endemic syphilis occurs predominantly among children, with onset usually occurring in children younger than 15 years and with equal sex distribution. Spread occurs most commonly within the family, and active disease can be manifest in more than one family member at any given time.

Pathogenesis and Pathology

T. pallidum subsp. *endemicum* usually enters the host through the oral mucosa. The small number of treponemes introduced into a susceptible host normally precludes the local multiplication and host inflammatory response required to produce a visible primary buccal lesion.²³ When a primary lesion does occur, it appears as a papule or ulcer resulting from a chronic inflammatory response to the proliferating organisms consisting of plasma cell, lymphocytic, and macrophage infiltration. Endothelial cell swelling of small blood vessels also is evident.

The organisms are carried to the regional lymph nodes within a few hours of entry, commonly through the oral mucosa portal. They multiply and elicit epithelial hyperplasia and plasma cell, lymphocytic, and macrophage infiltration, with resultant lymphadenopathy. Dissemination occurs through the circulation, and the organisms are carried to the skin, bone, oral mucosa, axillae, and anogenital regions, where they multiply and elicit a chronic inflammatory response characterized by a cellular infiltration, as seen in the lymph nodes. Vascular changes and perivascular cuffing are prominent.

The untreated early lesions heal as a result of mechanisms thought to involve humoral and cellular immune responses by the host,⁵⁸ and the disease enters into a state of latency. Maintenance of latency is thought to involve similar mechanisms. The occurrence of infectious relapses during the latent period still is uncertain.

The late lesions of endemic syphilis are strikingly similar to those of late-stage yaws. Late-stage disease and relapses (if they occur) may be caused by a hypersensitivity-induced mechanism similar to that postulated for the syphilitic gumma.^{21,23} Juxtaarticular nodules may occur and represent a nonspecific granulomatous response occurring near major joints.¹⁴ The rarity of cardiovascular and neurologic manifestations may be due to the slow acquisition of small numbers of organisms over a long time, which results in the immunologic protection of the heart and nervous system.^{23,36}

Clinical Manifestations

Endemic syphilis is a chronic, often debilitating disease characterized by early infectious secondary lesions; variable periods of latency; and late destructive lesions of cutaneous, subcutaneous, and bone tissues. As mentioned, primary lesions are rare. They appear usually on the breast or nipple as a papule or shallow ulcer similar to that seen in primary venereal syphilis after an approximate 3-week incubation period¹; they may persist for years before healing.³²

Even without the appearance of a primary lesion, generalized infection occurs as a result of early dissemination. The onset begins after an incubation period of 3 to 6 months and is characterized by the presence of highly infectious, relatively painless, ulcerative patches on the oropharyngeal mucosa, including the tongue, lips, palate, tonsils, and larynx, with accompanying regional lymphadenopathy. Involvement of the larynx usually results in hoarseness.¹⁴ Split papules or angular stomatitis occurs at the angles of the mouth. Osteoperiostitis of the long bones of the lower extremities, similar to that seen in yaws, is a common early manifestation causing nocturnal leg pains.¹⁴ Occasionally, axillary and anogenital secondary-type lesions result and consist of condylomata similar to those of yaws or dry papillomatous annular patches, with

accompanying axillary and inguinal lymphadenopathy. Disseminated papules that are indistinguishable from the papules seen in secondary venereal syphilis may occur. Other forms of cutaneous lesions can occur but are rare.

Untreated secondary lesions may persist for 6 to 9 months, at which time healing occurs because of the development of host immunity. This period of latency varies and, similar to yaws, may last for several years.

Most patients develop tertiary manifestations. Late lesions generally occur during adolescence or adult life and may resemble lesions seen in either late yaws or late-stage venereal syphilis. Gummas may affect any part of the body but commonly occur in the nasopharynx, skin, and bone, resulting in destructive, disfiguring, chronic ulcerations characteristic of gangosa or gangosa-like lesions. Late gummatous lesions can occur during childhood, possibly as a result of superinfection in an already infected host.²⁴ Bone involvement also is a common finding and results in painful lesions. This condition involves osteitis with gumma formation and, similar to yaws, periostitis affecting most frequently the long bones of the lower extremities. Bilateral synovitis, especially of the knees, occasionally may occur with concomitant juxtaarticular nodules.²⁴ The cardiovascular and neurologic findings common to venereal syphilis rarely occur in endemic syphilis; when clinical manifestations do occur, they usually are atypical and very mild.^{12,50}

Endemic syphilis reportedly has become “clinically attenuated” in Saudi Arabia. Previously florid, the classic disease seems to have been replaced by a milder form in which the number, severity, and duration of early and late lesions are reduced and seroreactive latent infection is increased.⁵⁰ The most common late manifestation observed in one study was painful osteoperiostitis of the legs affecting mainly the tibia and fibula. Researchers have postulated that attenuation is a result of improvement in hygienic conditions, better nutrition, and medical care.⁵⁰ This indicates the importance of attention to public health measures and the use of antibiotics in the eradication of the disease.

Prognosis

The main complication of endemic syphilis is the destructive gummatous lesions of the face and bones. Severely disfiguring and disabling, these lesions prevent the patient from working effectively in the community. Many of the bone lesions are extremely painful and incapacitating.

DIAGNOSIS

The development of point-of-care treponemal and nontreponemal antibody tests (described later) is an important advance in the clinical diagnosis of nonvenereal treponematoses in the field.⁶ However, differentiating the treponematoses from one another solely on the basis of serologic testing is currently untenable because of shared antigens.⁴⁸ Although tests based on molecular probes have been developed, these are still mostly research tools. A presumptive diagnosis is based largely on clinical presentation of the disease in an endemic area. Although darkfield examination of early lesions and lymph nodes permits visualization of treponemes, late lesions usually contain few, if any, organisms. The diagnosis of yaws in nonendemic areas or during periods of latency is difficult to make. The coexistence of yaws and endemic syphilis in certain geographic locations, together with their often identical clinical manifestations, renders darkfield and serologic assays useless for differentiating these diseases in such areas.⁵³ Similar limitations are applicable in differentiating venereal syphilis from yaws or endemic syphilis in nonendemic areas. Under these circumstances, the diagnosis can be based only on a careful history and epidemiologic data.⁵³

In tropical areas, numerous other diseases may be confused with yaws.^{28,53} Impetigo and chronic tropical ulcers are found frequently and may respond to penicillin or macrolide therapy. Ecthyma may produce ulcers that occasionally are similar to the ulcerative papillomas of yaws. The bacteria *Haemophilus ducreyi* has also been shown to produce lesions indistinguishable on examination to yaws.³⁹

Serologic testing is used in the diagnosis of both venereal and nonvenereal treponematoses. The rapid plasma reagin and Venereal Disease Research Laboratory tests are useful but may be nonreactive in early lesions. They are nonspecific nontreponemal studies using cardiolipin antigens that produce similar results in the presence of each

disease and cannot be used to differentiate between them. Care must be taken in the interpretation of nontreponemal tests in establishing the diagnosis because of the possibility of obtaining false-positive reactions among patients with nontreponemal diseases or conditions.⁴⁵ These tests are quantitative, however, and false-positive results usually have a titer of less than 1:4. After treatment has been given, a twofold or greater drop in titers usually signifies a successful outcome.

The treponemal tests, such as the fluorescent treponemal antibody absorption test, the *T. pallidum* immobilization test, and the *T. pallidum* hemagglutination assay, are specific but normally remain positive for life, and used alone they may not be helpful in diagnosing active cases. Combining nontreponemal and treponemal tests is helpful in establishing the diagnosis when there is a high pretest suspicion, when a false-positive nontreponemal test is likely, when a treponemal test is negative, or when there is a low pretest probability. In pinta, both types of tests may not become reactive until 4 months after the development of the initial lesion, whereas in yaws and endemic syphilis, both tests become reactive within the first few weeks of illness.

Although it may be less practical than serologic testing in remote and resource-poor areas, darkfield examination of fluid obtained from the initial serous exudates from cutaneous or mucous membrane lesions generally reveals the presence of treponemes. As the lesions become more chronic, treponemes become difficult to find. Silver impregnation of biopsy material from skin lesions or lymph nodes may reveal the organisms, but care must be taken in differentiating treponemes from tissue artifact.

The sequencing of the genomes of *T. pallidum pertenue* and *T. pallidum endemicum* has led to the development of polymerase chain reaction (PCR)-based molecular probes for the diagnosis of yaws and endemic syphilis. Another PCR assay has been developed to screen for point mutations in the 23S ribosomal RNA genes that are associated with macrolide resistance in strains of venereal syphilis. As yet, the genome for pinta has not been sequenced.^{11,64} Although PCR is highly sensitive and specific, it is not readily available to clinicians in remote areas. Newer treponemal tests using enzyme-linked immunosorbent assays (ELISA), chemiluminescence immunoassay (CIA), and enzyme immunoassay (EIA) have also been developed.⁴⁸ Point-of-care tests using fingerstick blood have been developed that employ the CIA technique. These have been shown to be accurate in the identification of antibodies to both treponemal and nontreponemal antigens. Point-of-care tests such as this will be an integral part of the WHO strategy to eradicate yaws because they eliminate the need for sophisticated laboratory equipment and transport of blood specimens, will aid in rapid diagnosis and differentiate between conditions causing similar symptoms, and can demonstrate response to treatment.⁶

TREATMENT AND PREVENTION

For decades, the treatment of choice for all treponemal infections was intramuscular benzathine penicillin G. Although effective, challenges in its use included the need for refrigeration and for intramuscular injection. A noninferiority trial of a single dose of 30 mg/kg of azithromycin versus benzathine penicillin in Papua New Guinea in children aged 6 months to 15 years with confirmed diagnoses of yaws showed that yaws can be cured in its early stages and can prevent transmission with both drugs.⁴⁷ Renewal of flagging efforts toward eradication with a single dose of an oral medication overcomes some of the disadvantages of the standard treatment with benzathine penicillin. Sterile protocols for intramuscular injections are not always easy to follow in remote areas, trained medical personnel are needed to administer the injections, penicillin allergy is often encountered, and penicillin requires refrigeration. Oral penicillin also is effective but requires 10 days of treatment, which makes compliance problematic. As a result, azithromycin at 30 mg/kg (up to 2 g maximum) is now the treatment of choice for yaws. Although not yet demonstrated in clinical trials, it is likely that endemic syphilis and pinta are similarly susceptible.

The efficacy and ease of administration of azithromycin led the WHO to adopt the Morges strategy in 2012 to eradicate yaws.⁵ There are two parts to this plan. First, mass treatment of all members of at-risk communities with azithromycin is performed. This has the advantage

of treating both active and latent cases of yaws, the latter of which can be difficult to detect. Second, surveys are to be conducted every 6 months after mass treatment in order to verify efficacy and to identify and treat persons with active yaws and their contacts.⁶³ The efficacy of this strategy in a geographically defined area was tested in a large clinical trial on an island of Papua New Guinea between 2013 and 2014. Within a population of 16,092, 82% of the population received a single dose of azithromycin. The prevalence of active yaws decreased from 2.4% to 0.3% one year after treatment, and the prevalence of latent yaws with high titer antibody positivity went from 18.3% to 6.5%. The treatment was generally well tolerated, and there was no evidence of resistance against azithromycin.⁴⁶ This study provided evidence that the Morges strategy is effective and can be used in future programs to eradicate yaws. Although no resistance to macrolides was noted, this still remains a concern. Another study looked at the prevalence of yaws in districts of Ghana where population treatment programs with azithromycin had previously been performed for trachoma. In patients examined, there was no evidence of yaws, indicating that the treatment programs may have interrupted the spread of yaws in these previously endemic areas. It was also encouraging that there was no evidence of the development of drug resistance to azithromycin.²²

For those with macrolide allergies or inability to tolerate these medications, intramuscular benzathine penicillin remains an effective treatment. Patients older than 10 years with clinical disease, those in a period of latency or in the incubatory stages, and contacts of cases should receive 1.2 million units of benzathine penicillin G intramuscularly in a single dose; children younger than 10 years of age should receive 600,000 units in a single dose by the same route.⁴⁰ Tetracycline is another alternative treatment for penicillin-allergic patients older than 8 years and not pregnant. The recommended dosage is 500 mg by mouth 4 times daily for 15 days (total dose of 30 g); children aged 8 to 15 years old may be given half the dose.⁵³ Although the newer tetracyclines have been used and are assumed to be equally effective, no information is available about clinical outcomes.

Therapy for yaws renders early lesions noninfectious in a few days, with complete healing achieved in 7 to 10 days. Recurrences after treatment may occur as a result of reinfection.²⁸ Late lesions heal more slowly after therapy and may require surgery. In endemic syphilis, infectious lesions disappear rapidly and relapses usually are prevented after therapy. The clinical response to therapy is remarkably slow in pinta. Primary and early secondary lesions take 4 to 6 months to disappear, whereas late secondary lesions require 6 to 12 months for complete healing to occur.⁵⁵ Hyperchromic lesions heal without residua, and hypochromic lesions often result in depigmented areas. Old achromic lesions usually remain intact without repigmentation.

In yaws and endemic syphilis, nontreponemal serologic titers may revert to nonreactive if the patient is treated early in the course of the disease. The longer the patient remains untreated, however, the more slowly conversion to seronegativity occurs, and treatment during the later stages may result in the persistence of high titers.⁵¹ Generally, the serologic response to therapy is absent or slow in pinta; nontreponemal tests may take years to decline after adequate therapy has been given.⁴⁴ In each of these diseases, treponemal tests remain reactive for life after the patient has received adequate therapy.

Improvement of living conditions and the general hygiene of the community, mass treatment of patients and contacts, and seroepidemiologic campaigns contribute significantly to the prevention of yaws. The Morges strategy formulated by the WHO recommends treatment of an entire endemic community for yaws irrespective of the number

of clinical cases and treatment of all active clinical cases and their contacts discovered on resurvey. When implemented, community-wide strategies have been remarkably effective, such as seen in an eradication program in Ecuador and the successful program in India. This underscores the need for accurate epidemiologic data throughout the world to properly identify and treat affected populations.^{62,63}

FUTURE CONSIDERATIONS

It is a tragedy that such easily curable diseases have yet to be eradicated. There remains a dearth of epidemiologic data because many governments have stopped collecting prevalence data since the presence of these diseases implies poor health conditions. The immigration of large numbers of people from endemic areas to developed countries means that clinicians everywhere must have an awareness of these diseases and keep them in their differential diagnosis of skin lesions. Important advances have been made strategically with the adoption of the Morges protocol by the WHO, diagnostically with the development of molecular probes and point-of-care dual antibody testing, and clinically with the confirmation that mass treatment with single dose azithromycin is both efficacious and practical. For eradication programs to succeed, prevalence data must be compiled, public health resources in affected countries need to be marshaled, and funding must be obtained. Simple measures, such as improved hygiene, education, and better access to health care in concert with other economic and public health programs, can greatly ameliorate the prevalence and severity of disease. The effective eradication campaigns of the 1950s and 1960s show that such programs can ultimately succeed given adequate resources and international cooperation.

Clostridial Intoxication and Infection

146

Martha Muller • Gary D. Overturf

Clostridia are obligate anaerobic, endospore-forming bacilli that usually are positive on Gram stain. Of the more than 200 species of *Clostridium*, at least 30 are potential pathogens in humans, mostly by virtue of their biologically active proteins (toxins). More than 25 lethal toxins produced by species of *Clostridium* have been defined in humans, including neurotoxins, enterotoxins, cytotoxins, necrotizing toxins, and enzymatic toxins.^{13,89} These ubiquitous organisms frequently are found in soil, sewage, decaying tissue, and the intestinal tract of humans and other animals.¹⁹ Clostridial species flourish in tissue with impaired vascularity and decreased oxygen tension.⁵³ The genus *Clostridium* has undergone significant revisions in taxonomy since 1994, which has resulted in a proposal for definitions of several clusters based on 16S rRNA gene sequences.⁵ Human disease caused by *Clostridium tetani* is discussed in Chapter 148.

BOTULISM

Botulism is an acute descending flaccid paralysis that results from the neurotoxin of *Clostridium botulinum*, which blocks neuromuscular transmission. Four naturally occurring clinical forms of botulism occur: (1) classic foodborne botulism, an intoxication caused by the ingestion of preformed botulinum toxin (BoNT) in contaminated food; (2) wound botulism, which results from elaboration of botulinum toxin in vivo after growth of *C. botulinum* in an infected wound; (3) infant botulism, in which botulinum toxin is produced in vivo in the gastrointestinal tract; and (4) botulism resulting from intestinal colonization in children and adults.^{5,25,50} Inhalational and iatrogenic forms of botulism have also been reported.⁶² Recently, the potential use of botulinum toxin as a bioterrorist agent has become an important concern. The Centers for Disease Control and Prevention (CDC) characterizes the toxin as a Category A biothreat item.⁵⁷ Infant botulism is discussed in Chapter 147.

Epidemiology and Etiology

Antigenically distinct types of botulinum toxins are designated by the letters A through H.³⁶ More than 40 years after the last toxin characterization, type H toxin was described in 2013 after its recovery from a patient with infant botulism.^{9,33} Disease in humans is caused by toxin types A, B, E, F (rarely), and possibly G.^{2,22,28,36,41,49,58,60} Types C and D cause botulism in animals.^{40,90} From 1973 to 1996, a median of 24 cases of foodborne botulism, three cases of wound botulism, and 71 cases of infant botulism were reported annually to the CDC.⁸⁷ This trend has continued recently; in 2009, the Centers for Disease Control and Prevention reported 10 cases of foodborne, 83 infant, and 25 wound or other source botulism cases.²⁴ In the United States, approximately 50% of foodborne cases are caused by toxin A and 25% each by toxins E and B. Type A occurs primarily in western states, and type B is seen more commonly in eastern states. Type E outbreaks occur more frequently in Alaska and the Great Lakes region. In addition, unique strains of clostridial organisms, other than *C. botulinum*, can produce botulinum neurotoxins and include *C. butyricum*, *C. barati*, and *C. argentinense*.⁹²

BoNT is considered the most potent and lethal of all naturally occurring compounds; the intravenous lethal dose for BoNT has been estimated to be 0.1 to 0.5 ng per kilogram of body weight, or an oral dose of 0.2 to 1 µg/kg. BoNT consists of a simple dichain composed of a heavy 100-kDa chain joined by a disulfide bond to a 50-kDa light chain. The toxin's light chain is a Zn²⁺-containing endopeptidase that

blocks acetylcholine-containing vesicles from fusing with the terminal membrane of the motor neuron, thereby resulting in flaccid paralysis.⁵⁴ It is heat-labile; 5 minutes of boiling destroys the toxin, and little remains after 30 minutes of exposure at 80°C (176°F). Neurotoxins are produced by *C. botulinum* at all temperatures at which growth occurs (31 to 48°C [37.4° F]). BoNT also is formed at all pH values at which growth occurs (pH 4.8 to 8.5), but it is unstable at pH values higher than 7.0. Toxin thus is produced only during active growth and released during lysis of bacterial cells. The presence of organisms in improperly processed acidic food, however, can allow toxin production to occur.^{41,90} Type E BoNT may be produced quickly in small fragments of fish exposed to air and at lower pH values and cooler temperatures than noted with other BoNT types.⁴⁰

Most outbreaks of botulism in the United States are traceable to home-processed foods; however, in recent years the proportion of cases that result from restaurant-associated outbreaks has increased significantly.⁸⁷ The most important food vehicles are vegetables, fish, fruits, and condiments. Type E botulism almost always is traceable to fish and fish products, but types A and B also may be involved in outbreaks related to this type of food. Recent outbreaks have been traced to unusual foods, such as potato salad and sautéed onions served by restaurants and commercial frozen pot pies mishandled at home.

Wound botulism results from infection of traumatized tissue by *C. botulinum* type A or B and subsequent production of toxin.⁶⁹ In the United States, approximately 80% of cases are caused by toxin A and 20% by toxin B.⁸⁷ Although infrequently reported, wound infection is a disease of pediatric concern; approximately half of the cases in the United States that occurred before 1991 involved children and teenagers, most of whom were boys with compound extremity fractures. In recent years, however, most new cases have occurred in users of contaminated injectable black tar heroin.^{5,28,87}

Pathophysiology

Botulinum toxin is absorbed from the proximal part of the intestine or an infected wound and is distributed hematogenously to the neuromuscular junction of motor neurons. The toxin irreversibly binds to presynaptic membranes, where it penetrates the plasma membrane by receptor-mediated endocytosis and the light chain of toxin (50 kDa) is internalized into the nerve cell through a protein channel. BoNT specifically cleaves proteins involved in vesicle trafficking of neurotransmitters, and exocytosis of acetylcholine is prevented. The prevention of neurotransmission results in clinically flaccid paralysis.^{40,41,90} The cranial nerves are affected earliest and often most severely. Death occurs mainly from respiratory muscle paralysis (asphyxia) or its complications, such as cardiac arrhythmia, aspiration, and pneumonia.²⁹ The clinical hallmark of botulism is an acute flaccid paralysis that begins with bilateral cranial nerve impairment of the muscles of the eye, face, head, and pharynx, descending symmetrically to involve muscles of the thorax and extremities.⁹⁵ BoNT, unlike tetanus toxin, does not enter the central nervous system (CNS). Recovery occurs by regeneration of terminal motor function and the formation of new motor end-plates. The lethal dose of botulinum toxin for humans is not known but can be estimated from primate studies; the dose of crystalline toxin lethal to a 70-kg human would be approximately 0.09 to 0.15 µg intravenously (or intramuscularly), 0.70 to 0.90 µg by inhalation, and 70 µg orally.⁸⁶

Clinical Manifestations

Because the pathogenesis of botulism involves the systemic absorption of BoNT and hematogenous dissemination with subsequent involvement of cholinergic synapses, virtually all forms of botulism have identical neurologic signs. The signs and symptoms of botulism are summarized in Table 146.1.⁸ The onset of illness varies from 12 to 72 hours after the implicated food is ingested, but it has been documented to occur as late as 108 hours after ingestion in some epidemics.⁸

Foodborne illness, or classic botulism, may be preceded by abdominal cramps, nausea, vomiting, or diarrhea. The neurologic illness begins as mentioned previously, as a descending symmetric motor paralysis first affecting muscles supplied by the cranial nerves.^{8,38} No sensory disturbance occurs, although vision may be impaired and hearing distorted because of cranial nerve involvement. Mental processes remain clear, but anxiety and agitation may be present. Fever is absent unless a secondary bacterial infection occurs. The triad of bulbar palsies (including a sluggish or absent pupillary response to light), lucid sensorium, and absent fever always should bring botulism to mind. Common symptoms include blurred vision, diplopia, dysarthria, and dysphagia. The degree of ocular involvement is quite variable; in severe cases, the pupils may become fixed and dilated. The mucous membranes of the mouth, tongue, and pharynx may be so dry that pain results, which may lead to the mistaken diagnosis of pharyngitis. Dizziness or vertigo may occur. Urinary retention may be seen, occasionally with stress incontinence.

Two thirds of patients have no gastrointestinal symptoms. In those who do, with type A or type B botulism the gastrointestinal manifestations are primarily abdominal pain, cramps, fullness, and diarrhea. However, after an initial period of diarrhea, constipation or obstipation may be

noted and, indeed, is more typical of the disease. In contrast to those with the other types, most patients with type E botulism first have gastrointestinal symptoms, including nausea, vomiting, substernal burning or pain, abdominal distention, and decreased bowel sounds. The most common signs encountered in botulism are respiratory impairment; specific muscle weakness or paralysis; eye muscle involvement, including ptosis; dry throat, mouth, or tongue; dilated, fixed pupils; and ataxia. Respiratory involvement, even aside from aspiration pneumonia, is a fairly common occurrence. Vital capacity is a more sensitive indicator of respiratory compromise than is measurement of blood gas. Postural hypotension, nystagmus, and somnolence may be noted.

The usual interval (incubation period) between the ingestion of food and the onset of symptoms is 18 to 36 hours, but it may be as short as 2 hours or as long as 8 days. In general, patients with shorter incubation periods are affected more severely and have a poorer prognosis. The shortness of the incubation period and the severity of illness correlate with the amount of BoNT ingested. Although the syndrome is similar for each toxin type, type A toxin has been associated with more severe disease and a higher mortality rate than has either type B or type E toxin.¹⁰⁴

The symptoms of wound botulism are similar to those of food botulism, but some important differences may occur.⁶⁹ Fever may or may not be present. Constipation occurs, but nausea and vomiting do not. Unilateral sensory changes in association with the trauma or infection may be noted. The wound itself may have grossly purulent drainage, but sometimes the wound shows no evidence of infection. The incubation period of wound botulism usually is 4 to 14 days.

In the event of intentional foodborne poisoning with BoNT, the signs and symptoms probably would resemble those of naturally occurring foodborne botulism.^{8,87} If the aerosolized BoNT from a bioterrorist attack were to be inhaled, the incubation period might be slightly longer, and gastrointestinal symptoms might not occur.^{8,87}

TABLE 146.1 Symptoms and Signs of Foodborne Botulism Types A and B

	% of Cases
Symptoms	
Dysphagia	96
Dry mouth	93
Double vision	91
Dysarthria	84
Fatigue	77
Arm weakness	73
Constipation	73
Leg weakness	69
Blurred vision	65
Nausea	64
Dyspnea	60
Vomiting	59
Dizziness	51
Sore throat	54
Abdominal cramps	42
Diarrhea	19
Paresthesia	14
Signs	
Alert mental status	90
Arm weakness	75
Ptosis	73
Leg weakness	69
Gaze paralysis	65
Facial palsy	63
Diminished gag reflex	58
Tongue weakness	58
Pupils dilated or fixed	44
Hyporeflexia or areflexia	40
Nystagmus	22
Ataxia	17

Differential Diagnosis

The differential diagnosis of botulism includes myasthenia gravis, cerebrovascular accidents, Guillain-Barré syndrome (particularly the Miller-Fisher variant), tick paralysis, paralytic shellfish poisoning, chemical intoxication, diphtheritic polyneuritis, psychiatric disease, and the Eaton-Lambert syndrome.^{40,90}

Ordinary bacterial food poisoning generally is not a problem in the differential diagnosis because of the absence of cranial nerve involvement. Chemical food poisoning may cause neurologic manifestations, but the signs almost always appear within minutes or at most hours after consumption of contaminated food. Atropine poisoning has a very rapid onset and is distinctive because of facial flushing and hallucinations. Shellfish and fish poisonings have a rapid onset and often cause characteristic paresthesias, tremors, and other signs. Mushroom poisoning results in severe abdominal pain, violent vomiting, diarrhea, and coma.

Myasthenia gravis usually spares pupillary oculomotor function. An edrophonium (Tensilon) test should be performed. Guillain-Barré syndrome can mimic botulism but usually shows ascending peripheral paralysis and, later, cranial nerve involvement. Muscle cramps, paresthesias, and an elevated protein content in cerebrospinal fluid (CSF) in the absence of cells help distinguish this disease. Electromyography may be extremely useful in differentiating botulism from atypical cases of Guillain-Barré syndrome. Because BoNT does not enter the CNS, abnormalities of the CSF are virtually never present.

The problem of identifying a case is complicated by reports of patients with features not characteristic of either botulism or the action of botulinum toxin, such as paresthesias, asymmetric weakness of the extremities, asymmetric ptosis, slightly elevated CSF protein, and a positive response to edrophonium. Some of these symptoms may be a consequence of the high anxiety that prevails in persons who know that they have eaten a food containing BoNT.

Specific Diagnosis

Confirmation of the diagnosis of botulism depends primarily on detection of botulinum toxin or the organism in the patient or in the implicated food or wound.^{40,90} Specimens to be examined for botulinum toxin include serum, gastric contents or vomitus, feces (at least 20 to 50 g

when possible), and exudates from wounds and tissues. These specimens, particularly blood specimens, should be obtained as soon as possible and before antitoxin is given. When feasible, at least 15 to 20 mL of blood should be drawn into a large vacuum tube and sent without separation of the serum to the nearest laboratory capable of performing the mouse neutralization test and other tests for toxin. On suspicion of clinical botulism, state health departments and the CDC should be consulted immediately regarding appropriate specimen collection and transport and the appropriate laboratories to which samples can be sent. The CDC can be contacted for general information at 800-232-4636, available Monday through Friday, 8 AM to 8 PM Eastern time, and the CDC Emergency Operations Center is also available for consultation and provision of therapeutic materials at 770-488-7100 (current information available at <http://www.cdc.gov>).

Specimens should be refrigerated (4°C [39.2°F]) and be examined as quickly as possible after collection. Whenever feasible, suspect food should be kept sealed in the original container. Sterile unbreakable containers should be used for other food samples. Specimens to be shipped to laboratories must be placed in leak-proof containers; packed with dry ice in a second leak-proof, insulated container; and marked "Danger, hazardous material." Extreme caution should be used in handling material that may contain botulinum toxin because even minute quantities of toxin acquired by ingestion, inhalation, or absorption through the eye or a break in the skin may cause profound intoxication and death.

Laboratory confirmation of suspected botulism should be attempted, even late in the clinical course. Detection of the organism itself may be achieved by culture or a variety of molecular methodologies. However, the most reliable assay for BoNT remains the mouse bioassay with type-specific neutralization of toxin with specific antitoxins.²⁹

Botulinum neurotoxin is detected in serum or stool specimens in approximately 46% of clinically diagnosed cases. When stool specimens also are cultured for *C. botulinum*, confirmatory evidence is obtained in approximately 70% of botulism cases.^{87,104} Thus, detection of *C. botulinum* toxin or organisms in the stool of a symptomatic person should be considered diagnostic.

Treatment

The mainstay of therapy for all forms of botulism is meticulous supportive care, with particular attention paid to the respiratory and nutritional needs of the patient and to anticipation of potential complications.^{40,41} Symptomatic persons known to have ingested toxin-containing food should be hospitalized, with careful monitoring of respiratory and cardiac function.

In cases of foodborne botulism, if the patient is seen early, protected induced emesis and gastric lavage may be considered to reduce the amount of unabsorbed toxin; in the absence of ileus, cathartic agents may be helpful. Magnesium-containing cathartic agents should be avoided because they may enhance the action of botulinum toxin.

Heptavalent antitoxin (types A to G; i.e., H-BAT) of equine origin frequently is considered in the management of foodborne botulism in adults, although conclusive evidence of its efficacy is lacking.^{40,95} In the past, trivalent (A, B, and C) and bivalent (A and B) were available, but since 2010 only the heptavalent material is provided by the CDC. Antitoxin is provided to neutralize circulating botulinum toxin molecules that are not yet bound to nerve endings. This material has been "despeciated" by the removal of the Fc fragment of the immunoglobulins, resulting in a material which is more than 90% Fab and F (ab) immunoglobulin fragments. Although antitoxin is recommended for treatment, the paralysis caused by irreversible binding of the neurotoxin cannot be reversed by administered antitoxins. The dose currently recommended in adults is one vial per patient as a single dose.⁸⁷ Recommendations for children will accompany the full instructions included from public health and CDC authorities. Hypersensitivity reactions have been reported in approximately 9% of persons treated with equine sera, so skin testing should be performed before administration of the antitoxin (recommendations for testing are provided by the CDC). Treatment of a single patient with suspected or proved foodborne botulism requires immediate notification of state and federal (CDC) health officials, who also are the antitoxin source, and the food responsible for the index patient's illness still may be available to other persons. The appropriate initial

contact is via the state health department. If this agency cannot be reached, the CDC should be contacted immediately (see the CDC telephone numbers in the earlier discussion of diagnosis). Presently, a human-derived botulinum antitoxin is available in the United States exclusively for the treatment of infantile botulism and is discussed in Chapter 147.

In the event of a potential exposure to a suspected contaminated food, the following procedures should be implemented. Locate all persons who ate the suspect food and determine whether anyone has signs or symptoms of botulism.⁴⁰ If patients are seen soon after the suspect meal, the use of gastric lavage, emetics, and cathartics deserves consideration. Antitoxin should be made available. Any samples of the suspect food that may remain should be collected and refrigerated. The health authorities should assist the clinician with these tasks. The fecal and serum specimens needed to establish the diagnosis should be obtained. If neurologic signs are present, one should try to identify defective neuromuscular transmission by electromyography. If neurologic signs are absent, the patient and family should be informed of the early signs of botulinum intoxication and be instructed to return at the first manifestation of ptosis, diplopia, blurred vision, dysphonia, dysarthria, or dysphagia. Because of the serious side effects of equine botulinum antitoxin, prophylactic administration of it to asymptomatic persons who have ingested food known to contain botulinum toxin generally is not recommended.⁵

When wound botulism is suspected, exploration and débridement of the site must be undertaken, ideally after the administration of antitoxin has begun. Arrangements should be made to obtain material for anaerobic culture in the operating room and antibiotic therapy begun there. High-dose penicillin 250,000 to 400,000 U/kg per day for 10 to 14 days is the drug of choice. Guanidine, aminopyridine, steroids, and intravenous immunoglobulin have been used to treat a small number of cases of foodborne and wound botulism, but convincing evidence of their efficacy is lacking. Metronidazole has been suggested as an alternative for penicillin, based on studies suggesting its enhanced efficacy in tetanus, but evidence for its effectiveness in botulism is not available.

Prognosis

With an emphasis on mechanical ventilation and intensive supportive care, the mortality rate from botulism has decreased steadily from 60% in the 1950s to 3% to 5%, and a mortality of less than 1% among hospitalized patients. It is lower with type B and type C disease than with type A19 and lower with any type in individuals younger than 20 years. An important factor is the dose of toxin ingested as reflected by the length of the incubation period. The longer the incubation period, the better the prognosis, whereas shorter incubation periods are associated with ingestion of larger doses and higher rates of morbidity and mortality. Thus, if the index case in an outbreak can be detected early, other patients exposed to the same food will have a much better prognosis. Recovery may be prolonged, and some symptoms (e.g., fatigability) may persist for as long as 1 year. Most patients recover entirely.

Prevention

Local and state health authorities and the CDC should be notified immediately of all suspected cases of botulism so that timely investigations can be undertaken. Although commercial products still are responsible for botulism occasionally, control measures taken by industry have done a great deal to prevent botulism from this source. Home canners still must be instructed regarding appropriate means for sterilizing containers and food preservation and for adequate cooking of food before serving.^{40,90} In canning, a pressure cooker must be used to obtain temperatures well above boiling to destroy spores of *C. botulinum* types A and B. For certain foods, a temperature of 116°C (240.8°F) is recommended. Spores of *C. botulinum* are destroyed at 120°C (248°F) after 30 minutes. Pressure cookers set at 15 lb will achieve this temperature, but correction for higher altitudes must be made. Home-canned foods should be boiled for 10 minutes before serving. Food containers that appear to bulge may contain gas produced by *C. botulinum* and should not be opened. The pentavalent botulinum toxoid vaccine has been used in military personnel to protect them from biologic warfare assault; given in three subcutaneous doses, it leads to detectable antibodies in 83% of subjects.²⁸

CLOSTRIDIAL INFECTIONS

Clostridia are encountered less commonly in infections than are non-spore-forming anaerobic bacteria, but these spore formers rarely may produce devastating disease. Overall, clostridia are present in 5% to 10% of anaerobic or mixed (aerobic and anaerobic) infections.^{17,34,40,97} Table 146.2 depicts the relative frequency of clostridial species from clinically significant infections at a single academic hospital.⁵ Surgical or traumatic events are reported to precede 90% of cases of clostridial infections.⁸⁴

Clostridium perfringens is the species encountered most commonly. It may be isolated in pure culture but more commonly is part of a mixed flora involving other anaerobes and nonanaerobes. Other species important clinically or encountered commonly (or both) include *C. novyi*, *C. septicum*, *C. bifermentans*, *C. histolyticum*, and *C. sordellii* (together with *C. perfringens*, these species commonly are referred to as the “gas gangrene group”); *C. tetani* (see Chapter 147); *C. difficile*, a major pathogen in pseudomembranous colitis; and a group of clostridia important in infections other than gas gangrene or myonecrosis (wound infection, abscesses, bacteremia, etc.)—*C. perfringens*, *C. ramosum*, *C. bifermentans*, *C. sphenoides*, *C. sporogenes*, and others.

Clostridia may be involved in a wide variety of infections throughout the body. Certain of these infections have a distinctive clinical picture and are discussed in this chapter. Many other infections, including peritonitis, intraabdominal infection, wound infection, soft tissue infection, and, occasionally, pleuropulmonary infection, CNS infection, and urinary tract infection, are not distinctive and will not be discussed specifically here. Emphysematous cholecystitis involving *C. perfringens* has distinctive features, but it is not encountered in the pediatric age group and thus is not discussed. Bacteremia involving *C. perfringens* may or may not have characteristic features. The distinctive intravascular hemolysis that may occur with *C. perfringens* bacteremia is discussed in connection with female genital tract infections caused by this organism.

Clostridial infections in children have revealed diverse species among 113 isolates in 107 specimens, including (in order of frequency) unidentified *Clostridium* spp. (33%), *C. perfringens* (12%), *C. inoculum* (5%), *C. ramosum* (4%), *C. botulinum* (3%), *C. difficile* (2%), and *C. butyricum*

(2%), as well as single isolates of *C. bifermentans*, *C. clostridioforme*, *C. limosum*, and *C. parputrifucum*.¹⁸ Most were from abscesses, peritonitis, bacteremia, and chronic otitis media, and many children had underlying conditions such as immunodeficiency, malignancy, diabetes, trauma, presence of foreign bodies, and prior surgery. Clostridia were isolated from 7% of all specimens processed for anaerobic bacteria, with frequent coisolation of *Bacteroides* spp., *Escherichia coli*, *Prevotella* spp., *Porphyromonas* spp., and *Fusobacterium* spp.

Epidemiology

The vast majority of clostridial infections are of endogenous origin. Even those secondary to trauma and contamination of a wound with foreign bodies usually involve *C. perfringens* or other clostridia from the host's flora, chiefly the intestinal tract. *Clostridium* spp. are ubiquitous in nature, with habitats in soil and the intestinal tracts of many animals, including humans and most other mammals. Clostridia even may be isolated from infant intestine as early as the first week of life, and by 6 to 20 months of age, the feces of infants contain approximately the same number of *C. perfringens* organisms as that of adults.⁵

Pathophysiology

The principal sites of normal carriage of *C. perfringens* and many other clostridial species in humans are the colon and vagina.^{5,40,41} These organisms may gain access to tissues through wounds, by perforation of abdominal viscera, or because of local disease such as tumor. The organism then may grow in tissues if the oxidation-reduction potential is low, host defense mechanisms are impaired, or both. Factors favoring anaerobic growth include the presence of abundant necrotic tissue, a poor blood supply, presence of foreign bodies, or previous multiplication of other bacteria in the wound leading to a lowered oxidation-reduction potential.

As noted, *Clostridium* spp. produced a wide range of toxins.^{51,92} *C. perfringens* produces at least a dozen different extracellular toxins or other factors that account for its pathogenicity.⁴⁰ The most important of the five major lethal toxins is α -toxin, a lecithinase and the main toxin responsible for destruction of tissue, hemolysis, and death. Other important factors include collagenase, hyaluronidase, leukocidin, deoxyribonuclease, and fibrinolysin. The enterotoxins produced by some strains of *C. perfringens* and *C. difficile* are important in the pathogenesis of certain gastrointestinal diseases.^{63,67} Gas gangrene, or clostridial myonecrosis, is characterized by profound toxicity, necrosis of muscle, edema, thrombosis of small vessels, gas bubbles in tissues, and minimal infiltration of leukocytes (probably caused by destruction of leukocytes at the site).

Clinical Manifestations

Gas Gangrene or Myonecrosis

Although other clostridia also are involved in gas gangrene, *C. perfringens* is the single causative species in approximately 90% to 95% of cases associated with trauma. Gas gangrene usually results from contamination of open wounds with contiguous injured muscle. Tissue destruction in gas gangrene is related to profound attenuation in blood flow as a result of activation of platelet responses by the α -toxin of *C. perfringens*.²⁰ Clostridial myonecrosis may occur in the absence of a traumatic wound, so-called spontaneous myonecrosis, and is caused by bacteremic seeding of muscle with either *C. perfringens*, *C. tertium*, or *C. septicum*.^{100,103} The last species is almost entirely associated with the spontaneous form of gas gangrene.⁶¹ In spontaneous myonecrosis, the source of the organism typically is the bowel, and the usual predisposing factors are mucosal tumors of the bowel or ulcerations produced by cytotoxic chemotherapy.⁴⁰ Additional reported risk factors for the development of spontaneous myonecrosis are intramuscular or subcutaneous inoculations, malignancies, immunocompromising conditions, and leukopenia.⁷⁰ Only a handful of cases of spontaneous myonecrosis in children have been described.⁷⁰

The typical case of clostridial myonecrosis is manifested by sudden appearance of pain in the region of a wound.⁴⁰ The pain increases in severity but remains localized to the infected area. Subsequently, local swelling and edema occur, and a thin hemorrhagic exudate appears. The pulse is very rapid, out of proportion to the mild elevation in temperature. Initially, the skin is tense, white, somewhat colder than

TABLE 146.2 *Clostridium* Species Most Frequently Encountered in Clinical Specimens at Indiana University Hospital Anaerobe Laboratory (1989–2001)^a

Species ^b	ISOLATES	
	No.	% of Total
<i>C. perfringens</i>	515	20
<i>C. clostridioforme</i>	421	16
<i>C. inoculum</i>	380	15
<i>C. ramosum</i>	357	14
<i>C. difficile</i>	287	11
<i>C. butyricum</i>	113	4
<i>C. cadaveris</i>	99	4
<i>C. bifermentans</i>	53	2
<i>C. sporogenes</i>	49	2
<i>C. glycolicum</i>	44	2
<i>C. septicum</i>	42	2
<i>C. tertium</i>	39	2
<i>C. sordellii</i> , <i>C. subterminale</i> , <i>C. paraputrificum</i> , <i>C. symbiosum</i> , and <i>C. baratii</i>	15-30	1

^aThe 2555 isolates do not include 270 isolates that did not belong to a recognized species (total of 2825 isolates), nor do they include *C. difficile* from fecal specimens.

^bSix or fewer isolates each of *C. beijerinckii*, *C. botulinum*, *C. carnis*, *C. celatum*, *C. coccoides*, *C. cochlearium*, *C. ghoni*, *C. hastiforme*, *C. histolyticum*, *C. indolis*, *C. limosum*, *C. malenominatum*, *C. novyi*, *C. putrefaciens*, *C. putrificum*, and *C. sphenoides*.

normal, and very tender. Bronze discoloration appears and increases with time. The process extends and becomes more severe, and the patient becomes toxemic. The skin becomes dusky or bronzed, and bullae filled with dark-red or purple fluid appear. Crepitus caused by gas may be noted, but the amount of gas produced generally is small. A peculiar sweet smell may be noted in some cases. Occasionally, a fetid odor that probably reflects the presence of a *Clostridium* organism other than *C. perfringens* may be present.⁴⁰ Toxic delirium and, later, overwhelming prostration and toxemia may develop. Some patients are alert and apprehensive, whereas others are apathetic. Later in the course of the disease, shock supervenes. At surgery, early changes in muscle consist primarily of edema and pallor, but increased reddening with mottled purple is present. The consistency of the muscle may be pasty or mucoid, and contractility disappears. Eventually, the muscle becomes diffusely gangrenous, dark greenish-purple or black, friable, and even liquefied. When bacteremia supervenes, mortality rates often exceed 50%.

Gram stain of the drainage or fluids or tissue obtained by biopsy is usually definitive, revealing gram-positive rods and a lack of inflammatory cells. Indeed, a paucity of inflammatory cells in tissue stains is highly indicative of infection with *Clostridium*.¹ However, recent studies indicate that the marked tissue destruction and absence of neutrophils with *C. perfringens* gas gangrene are caused by α -toxin-induced occlusion of blood vessels by platelets and neutrophils.¹⁹ The margin between healthy and necrotic tissue often advances several inches per hour despite appropriate antibiotic therapy, and radical amputation or debridement of necrotic infected tissue remains the best life-saving treatment. Hyperbaric oxygen has also been used as additional therapy,³⁹ but its efficacy is controversial, and its use often makes other supportive treatment difficult.

Soft Tissue Infection

C. perfringens and other clostridia also may be involved in less dramatic and less serious infections ranging from minor superficial infections to anaerobic cellulitis and necrotizing fasciitis.⁴⁰ Clostridial organisms in these infections may occur as single isolates, as part of a mixed flora consisting solely of anaerobic bacteria, or as part of a mixed anaerobic-aerobic bacterial flora. The clinical picture in these various infections is no different from that noted with other types of organisms and thus is not discussed further here.

Bacteremia and Sepsis

Clostridium spp. are important causes of sepsis, although infrequent in children. *C. septicum* is isolated only rarely from feces of healthy individuals but may be found in the appendixes of normal individuals, and more than 50% of persons whose blood is positive for this organism have some gastrointestinal anomaly such as colonic diverticulae or Meckel diverticulum. Additionally, malignancy has been reported in 50% to 90% of cases of *C. septicum* sepsis.⁷⁹ Many of the conditions most frequently predisposing to clostridial sepsis, such as gastrointestinal malignancy, vascular insufficiency or atherosclerosis, cirrhosis, neutropenia and pancreatitis, or uncontrolled diabetes, are rare in children and therefore, clostridial sepsis is rare in children.

Septic Abortion and Puerperal Sepsis

C. perfringens infections of the uterus usually occur after incomplete or traumatic abortions and are induced under nonsterile conditions.⁴⁰ More recently, *C. sordellii* has been more frequently associated with these infections. Occasionally, this type of infection will develop after spontaneous abortion, prolonged labor, ruptured membranes, or operative interference with pregnancy. Early symptoms include uterine bleeding, suprapubic and back pain, and chills, but often with little or no fever.^{40,41} The incubation period after the precipitating event usually is several days, but it may be less than 24 hours. In addition to vaginal bleeding, a foul-smelling, brown vaginal discharge containing necrotic tissue often is present. The uterus is tender, and the lower abdominal wall may be tense. Nausea, vomiting, and diarrhea may occur. Generalized peritonitis may complicate the picture. The most striking systemic manifestation of the disease, however, is massive intravascular hemolysis with hemoglobinemia, hemoglobinuria, and jaundice. Shock and acute renal failure may complicate the picture. Intrauterine gas formation

may be detected. Postnatal uterine infections resulting in gas gangrene of uterus are often rapidly fatal.

Neonatal Sepsis and Meningitis

A small number of cases of sepsis or meningitis (or both) caused by *Clostridium* spp. have been reported in newborns.^{42,44,71,72,93} Although some of these neonatal cases have been associated with invasive procedures or devitalized tissue, others have not had an obvious source.^{44,52,71} In several of these cases, the systemic infection involved both the mother and infant. The typical clinical picture in neonatal infections is one of fulminant septic shock, intravascular hemolysis, respiratory distress, and rapid death. Pneumocephalus may occur in the presence of meningitis.

Pseudomembranous Colitis (*C. difficile*)

Clostridium difficile is increasing as a pathogen in children despite high carriage rates in asymptomatic newborns and infants younger than 2 years. In addition, the epidemiology of *C. difficile* in children has been increasingly defined in recent years.^{7,15,58} The organism is the major cause of antibiotic associated diarrhea and pseudomembranous colitis.⁴⁵ Pathogenesis of this colitis is the production of two toxins, toxin A and B.^{35,37,98} Treatment and management of infections in children has been adapted from adult standards.¹⁰⁵ See Chapter 45 for a detailed description of the organism, current epidemiology in children, pathogenesis, and treatment of disease in children.

Food Poisoning and Other Enteric Infections

A usually mild, self-limited, and very common form of food poisoning may be caused by *C. perfringens*. Meat and meat products are the most common vehicles for such outbreaks.^{40,41,77} Food poisoning is caused by a heat-labile enterotoxin produced by *C. perfringens* type A. Disease is the result of ingestion of 10^8 or more vegetative cells that sporulate in the alkaline environment of the small intestine, producing the enterotoxin. The incubation period after ingestion of contaminated food varies from 6 to 30 hours but usually is 8 to 12 hours. The major symptoms are crampy abdominal pain and diarrhea. Stools are liquid but do not contain blood or mucus. Nausea may be noted on occasion, but vomiting and fever seldom are present. The illness typically lasts less than 24 hours but may be more severe in the very young or elderly.¹⁶

Rarely, *C. perfringens* also may produce a very severe type of enteritis known as enteritis necroticans. Although food poisoning is produced by *C. perfringens* type A, necrotizing enteritis involves the β -toxin of *C. perfringens* type C.⁶⁰ Consumption of excessive amounts of rich food by people normally on a low-protein diet who have decreased levels of digestive proteases seems to be an important background factor. Additionally, proteases may be blocked by ingestion of trypsin inhibitors found in sweet potatoes. In some cases, consumption of contaminated canned meat is involved. In Papua New Guinea, where this condition is known as "pigbel," enteritis necroticans in children is associated with traditional pig-feasting activities in which large quantities of pork are consumed. The disease is characterized by abdominal cramps, vomiting, shock, diarrhea (sometimes bloody), and acute inflammation of the small intestine with areas of necrosis and gangrene, particularly in the jejunum.⁸¹ A 12-year-old diabetic boy in whom enteritis necroticans developed after the ingestion of pig intestines (chitterlings) has been reported.⁸⁰

Miscellaneous Infections Caused by Clostridia

Fewer than 40 cases of septic arthritis attributable to *Clostridium* spp., including several pediatric patients, have been reported.⁴⁸ Anaerobic osteomyelitis caused by *Clostridium* also is a rare finding.⁴³ Aggressive surgical debridement and prolonged antibiotic therapy are warranted in the treatment of anaerobic musculoskeletal infections.⁸⁸

The clinical spectrum of clostridial bacteremia ranges from an asymptomatic patient with an incidental positive blood culture to fulminant sepsis syndrome.²³ Bacteremia with *C. septicum* is considered a unique syndrome associated with malignancies, particularly leukemia and colon cancer, and it has a devastating clinical course.^{47,64} Infections with this organism also have been linked to children with cyclic neutropenia.^{5,10,11,75} In a recent review of 28 pediatric patients with *C. septicum*

bacteremia, Caya²⁵ noted that all of them had underlying cancer or gastrointestinal disease. The overall mortality rate was 72%. Several cases of *C. septicum* infection occurring after *E. coli* O157–induced hemolytic-uremic syndrome have been described.^{6,12,55,66,82,83,102}

Clostridium sordellii infections have been associated with high fatality rates and most often have occurred after trauma, childbirth, and routine gynecologic procedures. They have been reported after medically induced abortions and intravenous drug injections. In one review of 45 cases, eight (18%) occurred after normal childbirth and five occurred (11%) after medically induced abortions, with a 100% case-fatality rate in this group.⁴ A few cases have occurred in children, including a 4-year-old child with arm trauma, a 17-year-old adolescent with omphalitis, a 12-year-old child with ear infection, an 18-year-old adolescent with a medically induced abortion, an 8-month-old with a pericarditis and associated pyopericardium with tamponade, and a 12-year-old boy with tuberous sclerosis.^{3,27}

Panophthalmitis involving *C. perfringens* or, occasionally, other clostridia is secondary to penetrating injury, usually with retention of a foreign body, but can also be seen without foreign bodies.^{40,101} Pain and loss of vision occur within 12 hours after the injury. By 18 hours, evidence of fulminating panophthalmitis is present and consists of chemosis and brawny swelling of the lids, proptosis, hypopyon, increased intraocular tension, gas bubbles in the anterior chamber, and necrosis of the wound margins. Intracranial infections involving *Clostridium*, usually as a result of penetrating trauma with items such as a lawn dart or an arrow, have been described.

Pneumatosis cystoides intestinalis can be produced in animals by *C. perfringens*, and this organism has been recovered from this process in humans.^{40,41} Pneumatosis cystoides intestinalis may be found in conjunction with toxic megacolon and neonatal necrotizing enterocolitis and as a complication of ileal bypass for obesity. Evaluation regarding the associating between *Clostridium* species and necrotizing enterocolitis and ultimate outcomes is ongoing.^{31,32} *Clostridium septicum* has been reported as causative of enterocolitis.²⁶

Clostridial species have also been implicated in infections after musculoskeletal allograft placement.⁵⁷

Clostridium has also been described as the causative agent of pyogenic liver abscess, especially sustained after blunt abdominal trauma. *Clostridium novyi*, *Clostridium clostridioforme*, *Clostridium bifermentans* and *Clostridium perfringens* have all been reported from pediatric patients with liver abscesses.^{2,68,73,76}

Specific Diagnosis

The diagnosis of gas gangrene must be made on clinical grounds. The presence of a gas-forming infection and recovery of *C. perfringens* from the wound do not establish the diagnosis of gas gangrene. The key to this diagnosis is demonstration of myonecrosis. Clostridial myonecrosis must be differentiated from other gas-forming soft tissue infections, which may or may not involve *C. perfringens*, and from other causes of myonecrosis. The sudden onset, extreme toxemia, and severe pain that are noted in clostridial myonecrosis represent important differential features. Entities such as anaerobic cellulitis and streptococcal myonecrosis have a gradual onset, slight toxemia, and less pain than seen with clostridial myonecrosis. Synergistic nonclostridial aerobic-anaerobic myonecrosis is a severe infection characterized by discrete areas of blue-gray necrosis of skin, along with extensive involvement of the underlying soft tissue and muscle and foul “dishwater” pus. Anaerobic cellulitis typically has much more gas and does not involve muscle.

In streptococcal myonecrosis, edema of the muscle is present initially, followed later by a hemorrhagic appearance.⁴⁰ Specimens for Gram staining and culture should be obtained from involved muscle rather than from the surface of the wound. Large gram-positive rods will be demonstrated on Gram stain in clostridial myonecrosis; no white blood cells may be demonstrable, or the white blood cells present may be distorted significantly as a result of the toxin of *C. perfringens* acting on them. Anaerobic-aerobic mixed cellulitis typically shows a mixture of organisms, which may include *C. perfringens*. Streptococcal myonecrosis reveals anaerobic streptococci, sometimes along with group A streptococci, *Staphylococcus aureus*, and other organisms.³⁰ In synergistic nonclostridial anaerobic-aerobic myonecrosis, *Bacteroides* organisms

seem to be key pathogens, together with anaerobic cocci and aerobic gram-negative bacilli.⁴⁰ Of importance when obtaining material for culture is to place it under anaerobic conditions or designated anaerobic transport media or devices for transport to the laboratory. Anaerobic blood cultures also should be performed.

Uterine infection by *C. perfringens* varies in severity from secondary invasion of necrotic material into the uterus or a dead fetus to invasion of intact uterine muscle producing myonecrosis and physometra.⁴⁰ Although bacteremia is a relatively uncommon finding in gas gangrene, uterine infection with *C. perfringens* frequently is accompanied by sepsis, which leads to the dramatic picture of intravascular hemolysis described earlier. Demonstration of severe hemolytic anemia in association with uterine infection essentially is diagnostic. Anaerobic blood cultures should be performed.

Clostridia, particularly *C. perfringens*, occasionally are isolated from the blood of a patient with a clinically benign course. The usual scenario is that a hospitalized patient has a single fever spike of unclear etiology and blood cultures are performed as part of the evaluation; by the time the culture becomes positive, no evidence of an infectious process is present. This transient and benign bacteremia probably originates from the colonic flora.^{15,21}

C. perfringens food poisoning usually is seen in the setting of a sizable outbreak.⁴⁰ The organism grows to high counts in the responsible food and then sets up an infection in the host, with production of enterotoxin in the colon of patients. Demonstration of large numbers ($>10^5$ /g) of *C. perfringens* in the implicated food and demonstration of the same serotype of *C. perfringens* in the stool of affected individuals and in the food are important in documenting the nature of the food poisoning. Enterotoxin also may be found in the stool of affected individuals, and the *C. perfringens* recovered from stool or food can be demonstrated to produce enterotoxin in vitro. Necrotizing enteritis caused by *C. perfringens* may be suspected by virtue of the dramatic clinical picture and confirmed by demonstration of *C. perfringens* type C in the stool or suspect food or demonstration of serum antibody to the β -toxin of the organism.

C. difficile–associated diarrhea should be suspected in children with diarrhea who have received antibiotics within the previous 2 months or whose diarrhea begins 72 hours after hospitalization.^{7,15,38,45,47,58,59,74} Typically, toxin testing of a single stool specimen will establish the diagnosis, but, occasionally, repeat testing or endoscopy may need to be performed. The finding of exudative plaques (pseudomembranes) and a hyperemic, friable mucosa by direct endoscopic visualization suggests the diagnosis of pseudomembranous colitis. Although *C. difficile* is isolated conveniently with use of a selective medium, distinction between toxigenic and nonpathogenic strains cannot be made. Its toxin B (cytotoxin) is identified most easily by tissue culture assay, which remains the gold standard for diagnosis of antibiotic-associated diarrhea.⁴⁰ A simple latex particle agglutination test for detection of *C. difficile* is available, although it is considered relatively insensitive and nonspecific and, for that reason, no longer is recommended.^{67,94,96}

In recent years, commercially available enzyme immunoassay (EIA) kits that detect toxin B or both toxin A and B have become the preferred method of diagnosis.^{14,96} The EIAs in general are easy to perform, relatively inexpensive, and specific. Polymerase chain reaction amplification tests for toxins A and B have been designed but are not available commercially.^{37,85,98}

Interpreting the significance of finding *C. difficile* or its toxins in very young patients with diarrhea is difficult because infants and toddlers have a high rate of asymptomatic carriage.^{35,56,99} Quantitation of toxin or organisms has not correlated with the presence or absence of symptoms. Consequently, once the possible presence of other diarrhea-producing pathogens (e.g., rotavirus, *Salmonella*) has been excluded, effort should be made to stop the presumptive precipitating antibacterial agent. If diarrhea with mucus or blood persists, endoscopy should be considered and specific therapy begun.

Treatment

The most important aspect of treating clostridial myonecrosis is immediate surgical intervention consisting of radical debridement and drainage and decompression of the fascial compartments.^{40,41} The wound should

not be closed after surgery. Of crucial importance is that all bits of necrotic muscle and other tissue be removed. Polyvalent gas gangrene antitoxin was never established firmly as being beneficial in the context of modern therapy, and this product no longer is available in the United States. Hyperbaric oxygen is recommended enthusiastically by some physicians, but no definitive evidence that its use reduces mortality rates has been shown. It does facilitate demarcation of a limb with impaired vascular supply, and it appears to slow or arrest local spread of the gangrenous infection. Clearly, however, hyperbaric oxygen must not be used as a substitute for any of the important principles of surgical management. Antimicrobial therapy also is important as an adjunct, with high-dose penicillin G (250,000 to 400,000 U/kg per day) being the drug of choice.^{40,41} In individuals allergic to penicillin G, clindamycin or metronidazole may be used. In addition, chloramphenicol is routinely active against all clostridia. The combination of penicillin and clindamycin has been used widely on the basis of experimental animal models that have shown enhanced efficacy with such a combination.⁹¹

Clostridial cellulitis is treated by incision plus drainage and antimicrobial therapy. Radical débridement is not necessary, but it is important to lay the tissues open to effect proper drainage and permit removal of all necrotic tissue.^{40,41}

Uterine curettage should be performed for diagnosis and treatment of postabortal or puerperal clostridial infections.⁴¹ Hysterectomy may be required if the myometrium is involved and if the patient's condition is deteriorating. At times, perforation of the uterus may be present without the typical clinical findings. Exchange transfusion has been recommended for sepsis caused by *C. perfringens* when significant intravascular hemolysis is present.

Food poisoning caused by *C. perfringens* is self-limited and requires no therapy. Antitoxin to the β -toxin produced by *C. perfringens* type C has been of considerable benefit in the treatment of necrotizing enteritis caused by this organism.

In any serious infection caused by *C. perfringens* or other clostridia, the usual supportive measures for shock, dehydration, anemia, and renal insufficiency are implemented as indicated.

Treatment of *C. difficile*-associated disease involves discontinuation of the offending antibiotic regimen when feasible. Isolates of *C. difficile* are susceptible to metronidazole and vancomycin. Oral or intravenous metronidazole 30 mg/kg per day in four divided doses is considered the drug of choice. With the recent and rapid increase in the recovery of vancomycin-resistant enterococci, many experts and the CDC suggest that oral vancomycin 40 mg/kg per day in four divided doses be used to treat *C. difficile*-induced diarrhea only in patients who are critically ill or those who do not respond to metronidazole.^{38,78,105} Intravenous vancomycin has not been shown to consistently effective. Orally administered bacitracin also may be useful, although some experts suggest that it may be less effective than metronidazole or vancomycin. Antimicrobial agents typically are administered for 10 days, but as many as 20% of patients may experience a relapse requiring a second course of treatment.⁶⁵ The use of cholestyramine or probiotics, such as *Saccharomyces* or *Lactobacillus*, in adult patients with multiple relapses has been advocated by some physicians, but such treatment has not been evaluated in children with disease caused by *C. difficile*.

Prognosis

The mortality rate in patients with gas gangrene varies between 15% and 35% and is worse when large muscle groups, such as those of the buttock, thigh, leg, and shoulder, are involved or when areas that are difficult to débride, such as the viscera and pelvis, are involved with disease. Clostridial cellulitis has a much better prognosis, but aggressive therapy still is important to minimize mortality rates. The mortality rate in postabortal clostridial sepsis remains 50% to 85%. *C. perfringens* food poisoning has an excellent prognosis, but mortality rates are significant with necrotizing enteritis caused by *C. perfringens* type C.

Prevention

Wounds involving areas with large muscle masses are particularly prone to gas gangrene, as are compound fractures, severe crush injuries, and injuries secondary to high-velocity missiles. Extensive laceration or devitalization of muscle tissue, impairment of the main blood supply to

a limb or large muscle group, and contamination by dirt or bowel contents all predispose to the development of clostridial myonecrosis. The most important aspect of prophylaxis by far is early and adequate surgical management.^{40,41} All devitalized tissue must be débrided; meticulous hemostasis is very important. Primary closure and tight packing of the wound should be avoided. All aspects of the wound must be drained adequately. If a cast must be applied, it should be bivalved from the outset. Hyperbaric oxygen is not indicated prophylactically. Antimicrobial prophylaxis, however, definitely is indicated. Penicillin is the drug of choice and should be given as early as possible after the injury occurs. Of emphasis is that antimicrobial prophylaxis is strictly adjunctive and far from adequate by itself. Bathing, particularly showering, and application of a compress wet with an iodophor for 15 minutes have been shown to reduce the skin count of *C. perfringens* significantly and minimize the likelihood of postoperative gas gangrene developing. This type of decontamination, of course, also may be useful in the management of traumatic wounds.

Prevention of clostridial uterine infection involves ensuring that all products of conception are removed during abortion and that retained portions of placenta are removed immediately after the third stage of labor. Prolonged labor should be anticipated when possible and analgesics administered judiciously. During labor, particularly with ruptured membranes, pelvic and rectal examinations should be kept to a minimum. During delivery, trauma should be minimized and lacerations repaired according to accepted surgical principles.

Proper sanitation in food-preparing facilities and adequate refrigeration are important safeguards against acquisition of *C. perfringens* food poisoning. In areas where necrotizing enteritis caused by *C. perfringens* type C is found with some frequency (such as in Papua New Guinea), a *C. perfringens* type C toxoid has been given with encouraging results.

Contact isolation for the duration of the illness is recommended for hospitalized children with *C. difficile*-associated diarrhea. Meticulous hand washing, the use of gloves for handling contaminated objects and fomites, environmental cleaning and disinfection, and limiting the use of antimicrobial agents have been advocated widely to control the transmission of *C. difficile* in health care facilities.⁴⁶

Infant Botulism

Jessica M. Khouri • Stephen S. Arnon

Of the three main forms of human botulism (foodborne, wound, and infant), infant botulism is the most recently recognized (1976) and since 1980 the most common form in the United States. Now recognized globally,⁷⁶ infant botulism results from a unique pathogenesis. Ingested spores of *Clostridium botulinum* germinate, colonize the infant's colon, and produce botulinum neurotoxin within it. The toxin is then absorbed, binds to peripheral cholinergic synapses, and causes flaccid paralysis. Knowledge of this intestinal pathogenesis resulted in discovery of novel pathogenic strains of *Clostridium baratii* and *Clostridium butyricum*, each of which produces a botulinum neurotoxin and causes infant botulism. Discovery of these strains enlarged the number of organisms known to cause the "intestinal toxemias of infancy," of which infant botulism is the prototype. Parenthetically, adults and older children rarely may become susceptible to infant-type (i.e., intestinal toxemia) botulism after broad-spectrum antibiotic treatment, intestinal surgery, or inflammatory bowel disease,^{9,35,45,52,60,136} or in association with a Meckel diverticulum^{49,118} or bone marrow transplantation.¹²⁶

HISTORY

Infant botulism is not a new disease but instead is a relatively recently recognized "emerging" infectious disease. The first laboratory-proven case of human infant botulism occurred in California in 1931, although it was misdiagnosed at the time.¹⁸ Decades later and well before the etiology of the disease was apparent, the characteristic clinical features of infant botulism had become evident to discerning observers. In 1974, Grover and associates⁵⁸ described nine patients from Pennsylvania with a neurologic syndrome of undetermined cause that from today's perspective almost certainly was infant botulism. The same idiopathic syndrome was recognized in southern California and was reported by Ramseyer and colleagues in 1976 to have a characteristic electromyographic pattern.¹¹⁴ A year later, Clay and associates linked their eight southern California patients to infant botulism.³⁶

The first report of botulism in infancy was provided by Pickett and colleagues in 1976.¹¹² Although the source of botulinum neurotoxin for their two patients was undetermined, the possibility of its *in vivo* production was suggested.^{92,112} The diagnosis of botulism in these and other California patients was established by identification of *C. botulinum* toxin and organisms in the infants' feces.⁹² Evidence also was obtained that ingested spores of *C. botulinum* had produced the toxin in the infants' intestinal tract.^{13,92,152}

In subsequent years the clinical spectrum of infant botulism was found to include mild outpatient cases and, in some but not all³⁰ locations, sudden unexpected death indistinguishable from typical sudden infant death syndrome.^{14,100,105,111} In 1985, a *C. baratii* strain that produced a type F botulinum neurotoxin was recognized belatedly as the true cause of a case of infant botulism that occurred in New Mexico in 1979,^{59,65} and in 1986, a *C. butyricum* strain that produced a type E botulinum neurotoxin was recognized as the cause of two cases of infant botulism in Rome, Italy.¹⁹ In 2014, a *C. botulinum* strain that produced both type B and a novel type H botulinum toxin was reported.^{22,41,46} These latter three novel clostridia were discovered only because they caused human infant botulism (rather than foodborne or wound botulism); their existence suggests that others like them await discovery.

ETIOLOGIC AGENT

Clostridium botulinum is a gram-positive, spore-forming, obligate anaerobe whose natural habitat worldwide is the soil. Consequently, *C. botulinum* is as ubiquitous as the dust on which it may travel; hence, its spores commonly are present on fresh fruits, vegetables, and other agricultural products such as honey. Members of the *C. botulinum* species are so diverse in their biochemical capabilities and nucleic acid profiles that they would not be grouped as a single species except for the similar neurotoxin molecule that each strain produces.^{63,135} The species *C. botulinum* is subdivided into four groups (I to IV) based on metabolic characteristics.^{63,135} Almost all cases of infant botulism in the United States have been caused by group I proteolytic type A or type B strains. However, unusual strains of *C. baratii* and *C. butyricum* that make botulinum toxins E and F also cause infant botulism.^{19,24,43,47,59,108,140,149} The entire 3.9-megabase (Mb) chromosome and a 16.3-kilobase (kb) plasmid within a *C. botulinum* type A strain were sequenced and found to contain 3650 and 19 predicted genes, respectively,¹²⁴ thereby launching the era of comparative genomic studies of this special bacterium.^{74,89,132,153} Whole genome sequencing has enabled comparison of *C. botulinum* strains at the nucleotide level.^{63,74,89,153}

In general, each vegetative cell of *C. botulinum* produces just one of eight distinguishable toxins, which have been arbitrarily assigned the letters A to H.^{22,41,46,87,110,135} A ninth toxin type of uncertain *in vivo* pathogenicity identified by genome database review and designated "serotype X" was recently reported.^{154–156} The eight toxin types are

operationally distinguished by polyclonal monovalent antitoxins raised against each of the toxin types; each monovalent antitoxin does not protect against any of the other seven toxin types. Hence, effective treatment of botulism occurs only when the antitoxin type (A-H) matches the toxin type (A-H) that matches the patient's illness. The different toxin types serve as convenient epidemiologic and clinical markers. Strains that produce two toxins have been isolated from patients (e.g., Ab, Af, Ba Bf, Bh); the capital letter indicates the toxin produced in greater amount.^{22,38,39,132} Subtypes of several toxin types have been identified by immunologic methods,^{71,72,77,144} by neutralization studies using monoclonal antibodies,^{6,134} and by toxin gene nucleic acid investigations.^{63,64,134} Each toxin molecule is a simple protein consisting of two polypeptide chains of approximately 100,000 (heavy chain) and 50,000 (light chain) daltons joined by a disulfide bond. The gene for botulinum toxin, *bont*, is part of an operon termed the "toxin gene cluster," which is a mobile genetic element that may be located in the chromosome, a plasmid, or a bacteriophage.^{63,131,132}

Botulinum toxin is the most poisonous substance known.⁵³ For this reason and because of the ease with which it may be produced, transported, and disseminated, the Centers for Disease Control and Prevention (CDC) has listed botulinum toxin as a Tier 1 ("mass casualty capable") potential bioweapon agent.^{1,16} By extrapolation from studies involving adult primates, the lethal dose in the bloodstream of humans is approximately 1 ng/kg body weight.^{16,53} The potency of the toxin for infants may be even higher because of the narrowness of their pharyngeal airway.¹⁴⁷

The basis of the phenomenal potency of the botulinum (and tetanus) toxins is enzymatic. The light chain of each neurotoxin is a zinc-containing protease that hydrolyzes one or more of three intracellular proteins needed for vesicle fusion and release of acetylcholine into the synaptic cleft.¹²⁰ The specificity of the toxins for peripheral cholinergic neurons results from their expression of a low-affinity ganglioside cell surface receptor to which the toxin attaches first that is then followed by its attachment to a second, high-affinity protein receptor that uniquely appears from the interior of the synaptic vesicle when it fuses with the terminal membrane to release acetylcholine.^{34,68,106,116}

PATHOGENESIS

Infant botulism is not the diminutive form of foodborne botulism, and, hence, the disease is not "infantile botulism." Rather, infant botulism results from a unique infectious disease pathway and was so named to emphasize that fact.^{13,92,152} Ingested spores of *C. botulinum* germinate, colonize the infant's colon, and produce botulinum neurotoxin in it.^{13,61,94,96,152} The toxin subsequently is absorbed and carried by the bloodstream to peripheral cholinergic synapses, where it binds and is endocytosed. The light chain then passes into the cytosol of the neuron, where it blocks the release of acetylcholine by enzymatic cleavage of "fusion complex" proteins.¹²⁰ Clinically, the most important peripheral cholinergic synapse is the neuromuscular junction; the toxin's action here results in flaccid paralysis and hypotonia. Preganglionic cholinergic synapses in the autonomic nervous system may also be affected.^{83,120}

By use of a mouse model system of intestinal colonization (in which the animals paradoxically remained free of symptoms), Sugiyama and colleagues^{29,96,141,142} demonstrated that the intestinal microbiome of adult animals ordinarily prevents colonization of the gut by *C. botulinum*. Administration of 10^6 type A spores failed to colonize the intestine of normal adult mice, whereas after treatment for 2.5 days with a combination of oral erythromycin and kanamycin, half the mice could be colonized by just 2×10^4 spores. When the antibiotic-treated mice were placed in cages with normal mice, they lost their susceptibility to intestinal colonization after 3 days.²⁹ (Mice normally exhibit coprophagia.) In addition, adult germ-free mice could be colonized intestinally by just 10 C. botulinum type A spores. When the germ-free adult animals were placed in a room with conventional mice (but not in the same cages), in 3 days the formerly germ-free animals became resistant to colonization by 10^5 spores.⁹⁶

In contrast to the experimental work with adult mice, normal infant mice were susceptible to intestinal colonization by *C. botulinum* spores.¹⁴¹ Like human infants, the normal infant mice were subject to colonization for only a limited period (7 to 13 days of age).^{11,141} Susceptibility of the infant mice peaked between days 8 and 11 in a pattern reminiscent of

the peaking of susceptibility seen between 2 and 4 months of age in human infant botulism (e-Fig. 147.1). The infective dose of spores for infant mice was much smaller than that of their antibiotic-treated adult counterparts; the 50% infective dose for normal infants was only 700 spores. In one experiment, just 10 spores were needed to colonize an infant mouse.¹⁴¹ The minimum infective dose of *C. botulinum* spores for human infants is not known, but from exposure to spore-containing honey, it has been estimated to be as low as 10 to 100.¹⁵

Recognition of the central role of the host's intestinal microbiome in determining susceptibility or resistance to colonization by *C. botulinum* has directed attention to its composition and to factors that may influence it.¹²⁸ Diet may be the most important of these factors. When compared to adult-type intestinal flora, the infant flora is simpler, with fewer genera and species.^{78,81,138,139} The dominant members vary, depending in part on whether the infant is fed only breast milk, only formula milk, or a mixture of the two.^{138,139} In addition, the composition of the intestinal microbiome is changed if solid foods, such as cereals, become part of the infant's diet. The normal human infant microbiome contains several bacterial species, mainly *Bifidobacterium* and *Bacteroides*, that in vitro can inhibit the multiplication of *C. botulinum*.¹⁴³

The onset of infant botulism occurs at a significantly younger age in formula-fed infants (7.6 weeks) than in breast-fed infants (13.7 weeks),¹² perhaps reflecting the earlier availability in formula-fed infants of suitable ecologic niches^{12,84,138,139} and the formula-fed infants' lack of the immune factors (e.g., secretory IgA, lactoferrin, leukocytes) contained in human milk.^{7,8,50,55} Moreover, introduction of solid foods may "perturb" the intestinal microbiome¹³⁹ and thereby assist in colonization with *C. botulinum*.^{8,11,84,139}

An additional physiologic risk factor for infant botulism is slower gut motility, as measured by the frequency of defecation before the onset of illness.^{123,137} Less than one bowel movement per day is a risk factor for both breast-fed and formula-fed infants, but this factor occurred in just 50% of cases.¹²³ Whether a Meckel diverticulum may predispose to the development of infant botulism caused by *C. botulinum*, as it appears to do for infant botulism caused by *C. butyricum*, is not known.^{47,49,118}

EPIDEMIOLOGY

Any discussion of the epidemiology of infant botulism should be prefaced by the caveat that almost all presently available information is derived from study of only part of the clinical spectrum, namely, hospitalized patients. Accordingly, current perspectives may need to be modified as the outpatient and sudden death parts of the clinical spectrum become more completely characterized. In addition, the perceived incidence remains more a reflection of physician awareness and access to diagnostic testing than the actual occurrence of disease. Somewhat more than one third (37.8%) of US cases have been reported from California, which has the largest number of births of any state. However, California does not have the highest incidence of infant botulism once adjustment is made for differences in annual births (Table 147.1). Notably, eight of the 12 states with the highest incidence are located west of the Rocky Mountains, and six of the eight are contiguous. The four eastern states with the highest incidence also are contiguous.

A unique epidemiologic feature of infant botulism is its age distribution, which, perhaps coincidentally, is virtually identical to the age distribution of sudden infant death syndrome (see e-Fig. 147.1).^{11,14,31,137} Almost all US cases (99.7%) of infant botulism reported to date have occurred in children younger than 1 year old. Some 88.7% of cases have occurred in the patients' first 6 months of life, 11.0% were distributed over the subsequent 6 months, and just 0.3% have occurred between 53 and 72 weeks of age. The youngest known patient was only 38 hours old at onset (and had illness caused by *C. baratii* type F toxin),²⁴ whereas the oldest was 72 weeks old at onset. The illness has occurred in all major racial and ethnic groups and in approximately equal proportions in males and females. A national seasonality is not evident. In California more cases have occurred in the six warmer, drier months (May to October, 58%) than in the six cooler, wetter months (November to April, 42%).

Infant botulism has been reported from all inhabited continents except Africa. In the United States, with 53 exceptions (1.5% of cases), all hospitalized cases known as of December 2015 were caused by either type A or type B botulinum toxin. All 50 states have reported infant

e-FIG.147.1 Age distribution of infant botulism and sudden infant death syndrome (SIDS).

TABLE 147.1 Cases and Incidence of Infant Botulism: Top 12 States in Incidence, United States (1977–2014)

^aPer 100,000 live births per year.

botulism; California (1976) was the first and Rhode Island (2008) was the last. In general, the distribution of cases by toxin type has paralleled the distribution of toxin types in US soil,^{90,129} with type B cases predominating from the Great Plains eastward and type A cases from the Rocky Mountains westward.

The 53 exceptional cases resulted from a variety of toxin types. Three cases in California and in Iowa, two in Colorado and Ohio, and one each in Idaho, Massachusetts, New Mexico, Texas, Virginia, Washington, and Wisconsin resulted from type F toxin produced by neurotoxicogenic *C. baratii* strains.^{24,59,65,97,108} Twenty-three cases were caused by *C. botulinum* that produced mostly type B and some type A toxin (designated type Ba), and 11 cases resulted from Bf strains. One case caused by both *C. botulinum* type A and type B from today's perspective probably resulted from either a Ba or Ab strain.¹³² Five patients with Bf illness lived in California,²¹ one lived in New Mexico, and four lived in Texas, whereas the 11th patient had traveled from California through New Mexico to Texas immediately before onset of the illness. Two type Bf cases occurred in the United Kingdom.¹³³ The only *C. baratii* type F cases reported outside the United States occurred in Canada and Hungary.¹⁴⁹ In Illinois in 2008, a type E case caused by *C. botulinum* occurred,⁸⁶ and in Arizona in 2006 a type E case caused by *C. butyricum* was recognized.⁴³ Five *C. butyricum* type E infant botulism cases were reported from Italy, two from Ireland, and one each from the United Kingdom and Japan.^{3,19,47–49,125}

Potential environmental sources of *C. botulinum* spores have been identified in many locales. The soil in Pennsylvania,⁸⁴ soil and cistern water in Australia,⁹⁹ untreated well water in Japan,⁷⁵ vacuum cleaner dust in Finland,¹⁰⁵ and soil and vacuum cleaner dust in California¹¹ obtained from case homes were found to contain *C. botulinum*, with the toxin type (A or B) in each instance matching the toxin type of the infant's illness. In addition, *C. butyricum* type E isolated from pet terrapin samples and their commercial food was associated with two cases in Ireland.¹²⁵ However, despite the foregoing, it deserves emphasis that for most cases of infant botulism, no source of *C. botulinum* spores is ever identified, even circumstantially. In these cases illness probably was acquired by swallowing spores adherent to airborne microscopic (invisible) dust.

Approximately one fifth (876 of 4302; 20.4%) of all known global infant botulism cases between 1976 and 2015 have been recognized from 34 countries other than the United States.⁷⁶ Of these cases, Argentina has reported the largest number (610),⁸⁵ followed by Australia (42), Canada (41), Italy (32), Japan (31), Spain (22), United Kingdom (16), Germany (14), France (8), Denmark (7), and Israel (5). The remaining countries have reported five or fewer cases each.⁷⁶ The non-US cases occurred in Europe (18 countries), Asia (3), the Middle East (5), North America (2), South America (3), and Australia.⁸⁸ The small number of reported cases from most non-US countries most likely reflects limited physician awareness of the disease and limited access to specialized diagnostic testing laboratories, as well as actual variation in disease incidence.⁷⁶

Geographic clustering has been noted.^{38,89} In Pennsylvania, 43 of 53 cases in the period 1977 to 1983 occurred in four suburban counties that form an arc bordering the city of Philadelphia.^{82,84} In Colorado, three type A cases occurred in three separate families in a small town with approximately 30 annual births over a 3-year period. Two of the infants had used the same crib sequentially; environmental samples, including the crib, soil, and household dust, yielded *C. botulinum* type A.⁶⁷

In a 35-year surveillance period in California both geographic (2 type A, 3 type B) and geographic-temporal (2 type A, 3 type B, 1 type A(B)) clustering was recognized (e-Figs. 147.2, 147.3, and 147.4).³⁸ In addition, two type A cases occurred 5 years apart in the children of two California families who lived one house apart. In another California family two successive infants each acquired type A infant botulism, but the third child born in sequence did not. Soil and dust specimens from the house where all three infants lived contained *C. botulinum* type A.

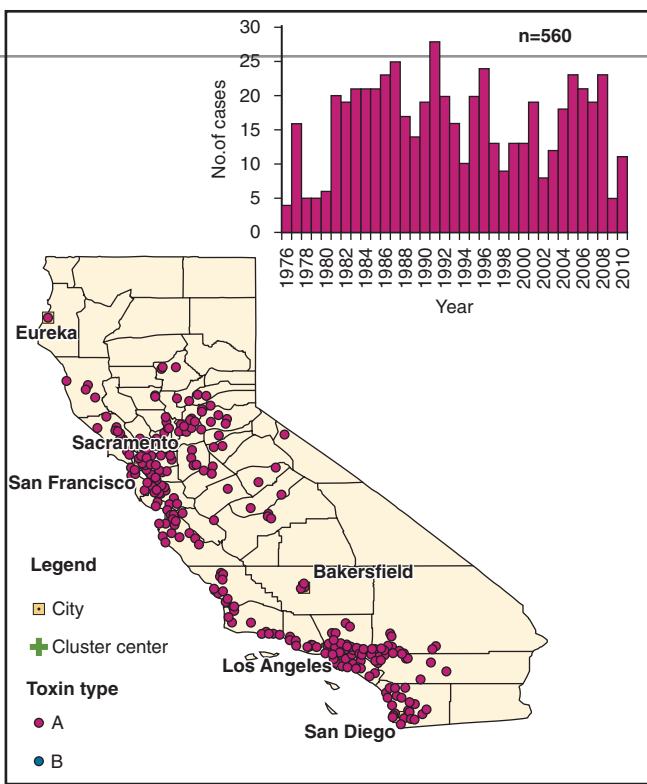

The role of breast-feeding and formula-feeding as factors possibly predisposing to illness remains unsettled. All studies to date have identified an association between being breast-fed and being hospitalized for infant botulism.^{7,12,82–84,98,137,146} This finding has resulted in one perspective that holds that breast-feeding predisposes to the development of illness,^{82–84,137} whereas the other perspective holds that breast-feeding slows its onset sufficiently to permit hospitalization to occur.^{7,8,11,12} Among hospitalized patients in California, the mean age at onset of botulism in formula-fed infants (7.6 weeks) was significantly younger and about half that of breast-fed infants (13.7 weeks).¹² In addition, all California patients with fulminant-onset infant botulism who stopped breathing and died at home were formula fed.¹² The relative susceptibilities of formula-fed and breast-fed infants to infant botulism and the resultant severity of their disease may reflect differences in availability ecologic niches for *C. botulinum* in the intestinal microbiome, differences in immune factors (e.g., lactoferrin and secretory IgA) contained in human milk but not in formula milk,⁵⁵ or other differences not identified yet.

Probably few, if any, patients with infant botulism acquire *C. botulinum* spores from infant formula, despite isolation in the United Kingdom of *C. botulinum* type B from powdered infant formula consumed by a patient with type B infant botulism.^{28,70} However, the capacity of powdered infant formula (a nonsterile product) to serve as a vehicle of clostridial spores was identified in a study of US commercial powdered infant formulas that found a dozen different clostridial species in them, including *Clostridium sporogenes* (the functional equivalent of atoxigenic proteolytic *C. botulinum*).²³ In addition, the possibility that an infant patient may have foodborne botulism needs to be kept in mind because foodborne botulism caused by home-prepared baby food has occurred.^{5,25}

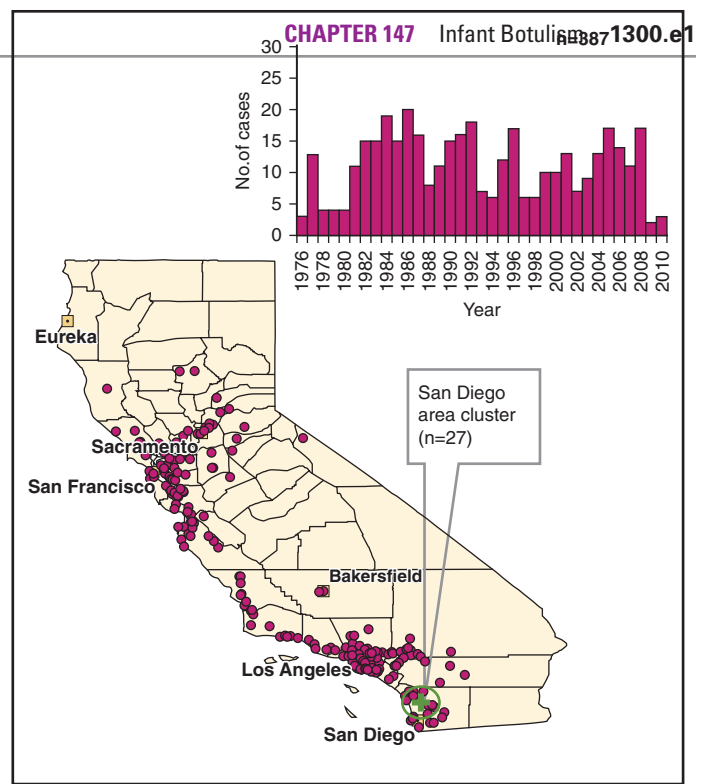

Honey is the one dietary reservoir of *C. botulinum* spores thus far definitively linked to infant botulism by both laboratory and epidemiologic evidence.^{11,15,20,62,66,73,93,104,117,142} More than 35 instances worldwide are known in which *C. botulinum* spores have been found in the actual honey fed to the affected infant before the onset of illness. In each instance, the toxin type (A or B) of the spores in the honey matched the toxin type of the *C. botulinum* that caused the infant's illness; the probability that such perfect concordance occurred by chance is less than 1 in 10 billion. Occasionally, *C. botulinum* has been isolated from honey in which the spore toxin type in the honey did not match the toxin type of the infant's illness^{20,47}; in such instances, the conclusion is that the honey was not the source of the infective spores.

C. botulinum spores have been found in honey from the United States, Argentina, Australia, Brazil, Canada, China (Taiwan also), Denmark, Finland, Hungary, Italy, Mexico, Norway, Spain, Japan, and Central America,^{15,20,62,66,73,93,101–104,121,142} and recently, in the United Kingdom in honeys fed to two patients with infant botulism.^{2,57,130}

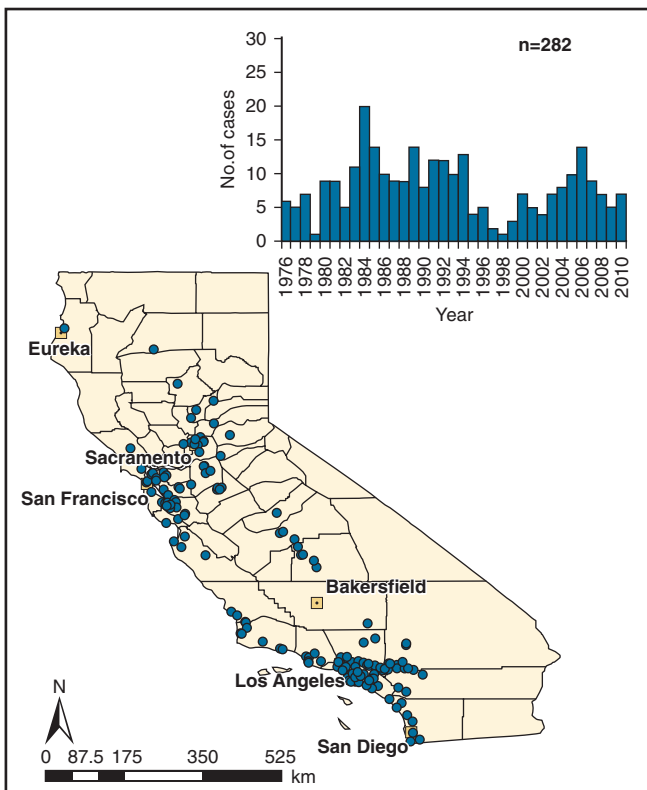

In general, only low concentrations of *C. botulinum* spores have been found in honey (≤ 1 spore/g),^{93,102} with the occasional higher concentrations (e.g., 36–60 spores/g) thought to result from multiplication of *C. botulinum* in dead bees and bee pupae.¹⁰¹ Toxin type A, B, C, and F spores all have been found in honey, with some of these toxin types linked to the geographic origin of the honey.¹⁰² For these reasons and because honey is not nutritionally essential, all major pediatric, public health, and honey industry agencies in the United States have joined in the recommendation that honey not be fed to infants. In 2000, several brands of honey sold in the United States began to carry

e-FIG. 147.3 Occurrence and distribution of A(B), bivalent (Ba, Bf) and rare strains of *C. botulinum*. (A) All A(B) California IB patient isolates ($n = 66$) located to six multimember and five singleton clades. One California 3-year-old intestinal toxemia patient isolate and two WB isolates not depicted. (B) The second-largest A(B) clade ($n = 23$) included 20 California patients and contained a geographic-temporal cluster of three patients near Bakersfield. (C) BoNT/Ba ($n = 17$), BoNT/Bf ($n = 3$) and *C. baratii* F ($n = 2$) California IB patient isolates. (D) Clade of 12 BoNT/B, /Ba and /Bf patient isolates. Geographic-temporal clusters determined using the Kulldorff spatial-scan statistic (see Kulldorff M. Bernoulli, discrete Poisson and continuous Poisson models: a spatial scan statistic. *Comms Stat Theory Methods*. 1997;26:1481-1496). *BoNT*, Botulinum neurotoxin; *IB*, infant botulism; *WB*, wound botulism. (From Dabritz HA, Hill KK, Barash JR, et al. Molecular epidemiology of infant botulism in California and elsewhere, 1976-2010. *J Infect Dis*. 2014;210[11]:1711-1722.)

e-FIG. 147.4 Geographic and geographic-temporal clusters of California IB cases between 1976 and 2010. (A) BoNT/A clade of 23 patient isolates with a geographic-temporal cluster centered near Sacramento. This clade also contained one vacuum cleaner dust and two soil isolates (not shown). (B) BoNT/B clade of 10 California patient isolates that clustered in the east San Francisco Bay area. The sole outlier patient lived in a central coastal county, had not traveled, and had been fed nonsterile solid foods. This BoNT/B clade also contained one soil isolate (not shown). (C) BoNT/B clade of 30 California patient isolates with a geographic-temporal cluster that occurred in southern California, 1992–1994. Note the absence of this particular *C. botulinum* type B strain in California patients before 1992 and after 1999, with 97% of the cases in the clade having occurred in the 4 years 1992–1994. (D) BoNT/B clade of 10 California IB patient isolates with a geographic-temporal cluster in southern California (one WB patient from 1999 not shown). All IB cases occurred in 2008–09 except for the 1986 case, who was driven through the Los Angeles basin (center of cluster) 2 weeks before onset of illness when the family moved from San Diego County to the San Francisco Bay area. Geographic-temporal clusters were determined using the Kulldorff spatial-scan statistic (see Kulldorff M. Bernoulli, discrete Poisson and continuous Poisson models: a spatial scan statistic. *Comms Stat Theory Methods*. 1997;26:1481–1496). BoNT, botulinum neurotoxin; IB, infant botulism; WB, wound botulism. (From Dabritz HA, Hill KK, Barash JR, et al. Molecular epidemiology of infant botulism in California and elsewhere, 1976–2010. *J Infect Dis*. 2014;210[11]:1711–1722.)

a warning not to feed honey to infants; an equivalent label first appeared on British honey in 1996.

In addition to honey, hundreds of traditional and nontraditional infant food items, including formula milk, have been examined and found not to contain *C. botulinum*.⁹¹ However, in instances not associated with illness, *C. botulinum* spores have been found in raw sugar and molasses but not in refined sugar¹⁰³ and in herbal (chamomile) tea²⁶ and other herbal preparations.^{27,76}

Discussion of the possible role of corn syrup in infant botulism is necessitated by two reports. In 1982, the US Food and Drug Administration (FDA) found *C. botulinum* type B spores in approximately 0.5% (5 of 961) of previously unopened retail samples of light and dark corn syrup⁷⁶; the manufacturer then made changes in the production process. In 1989, the federal CDC reported the results of a 2-year epidemiologic study of US cases from all states except California.¹³⁷ By subgrouping patients by age and using logistic regression modeling techniques, a statistical association was obtained among the triad of exposure to corn syrup, breast-feeding, and age at onset of 2 months or older.^{107,137}

In contrast to these reports, a 1988 Canadian survey found no *C. botulinum* spores in 43 samples of corn syrup.⁶² A 1991 FDA market survey of 783 syrups (354 of which were light corn syrup and 271 were dark corn syrup) concluded that none contained *C. botulinum* spores.⁷⁹ A California study (unpublished) of 103 corn syrups, 72 of which had been fed to infants who subsequently became ill with infant botulism, did not find *C. botulinum* in any sample. Moreover, a 1979 epidemiologic study that simply compared rates of exposure to corn syrup in 41 cases and 107 control infants identified feeding of corn syrup as a significant protective factor against type A infant botulism.¹⁵ The explanation offered for the latter observation was that if a parent chose corn syrup as a sweetener for the infant, the child was unlikely to have been fed honey as a second sweetener. Thus, on the basis of the available evidence, corn syrup appears not to constitute a source of *C. botulinum* spores or a risk factor for the development of infant botulism.

CLINICAL MANIFESTATIONS

Like other infectious diseases, infant botulism displays a spectrum of clinical severity.^{8,11,14,83,84,94,111,122,146} To date, almost all patients with recognized disease have been sufficiently hypotonic and weak to require hospitalization. Consequently, the present picture of infant botulism is derived from hospitalized patients. However, outpatients who displayed only a few days of lethargy, poor feeding, and some decrease in frequency of bowel movement have been detected by alert physicians familiar with the more “classic” illness. At the opposite end of the clinical spectrum are patients whose “catastrophic presentations” obscured and delayed establishment of the correct diagnosis^{95,105} and those few cases for which the history and clinical findings were indistinguishable from typical cases of sudden infant death syndrome (SIDS, crib death),^{14,105,111} approximately one in 20 of which (in California) appears to result from fulminant infant botulism.^{11,14}

The onset of infant botulism ranges from the insidious to the abrupt. At one extreme are patients who were nursing normally 6 hours before becoming so floppy that acute meningitis was the diagnosis at initial evaluation, and at the other extreme are patients who returned to their physicians four times in a week as the signs of illness gradually became apparent. Although rare, illness caused by *C. baratii* type F appears to be generally characterized by the triad of very young age at onset, rapid onset, and profound paralysis.^{24,97,108} Equally rare, illness caused by *C. butyricum* type E may be manifested as a paradoxically rigid abdomen and associated bowel colonization with *Clostridium difficile*.^{47,48}

In the “classic” case of infant botulism, the first sign of illness almost always is constipation (defined as 3 or more days without defecation in a previously regular infant), yet the constipation often is overlooked. A few patients (<5%) will not have a history of constipation. Usually, a mother first notices listlessness, lethargy, and poor feeding, together with breast engorgement if the infant had been nursing. The increasing weakness over the ensuing 1 to 4 days typically brings the infant to medical attention.

Botulism is manifested clinically as a symmetric, descending paralysis. Early in the course, weakness and hypotonia characterize the illness,

and the remainder of the physical examination not involving the neuromuscular system is normal. The first signs of illness are found in the cranial nerves; a patient cannot have infant botulism without having bulbar palsies. The typical patient has an expressionless face, a feeble cry, ptosis (evident when the eyelids must work against gravity), poor head control, and generalized weakness and hypotonia (Fig. 147.1). Eye muscle paralysis varies, with the pupils often at mid position and initially briskly reactive. However, fatigability of the pupillary light reflex and extraocular motility is also often present; these are pathognomonic signs and should be sought at presentation (Box 147.1).³ The gag, suck, and swallow reflexes are impaired, as is the corneal reflex if tested repetitively. Deep tendon reflexes frequently are normal at initial evaluation and diminish subsequently as the paralysis extends and increases. The “frog’s legs” sign is often observed. Patients are afebrile unless a secondary infection (e.g., aspiration pneumonia) is present.

Most laboratory and clinical studies are normal. At admission, the child may have evidence of mild dehydration and fat mobilization because of diminished oral intake. Occasionally at admission, the cerebrospinal fluid (CSF) protein concentration becomes elevated because of the mild dehydration. If infant botulism is suspected soon after admission, electroencephalography, computed tomography, and magnetic resonance imaging are seldom required. However, if performed, these examinations yield nonspecific or normal results. Electromyography may offer rapid bedside confirmation of the clinical diagnosis.^{40,44}

The definitive diagnostic laboratory study is examination of feces for the presence of *C. botulinum* organisms and toxin, which is the only certain way to identify the toxin type (A, B, or other) responsible for the illness. Small amounts (<5 mouse LD₅₀/mL) of botulinum toxin can sometimes be identified in serum specimens if collected early in the course of illness.^{19,47,61,85,109,145,148} In one US report almost one patient in eight had toxin demonstrable in serum.⁶¹ Clinically suspected cases that lack an identified toxin type are not included in official tallies of infant botulism.^{33,32,76}

The usual hospital course of *untreated* infant botulism has certain general features.^{8,69,84,122} After the increasing weakness has necessitated admission, the weakness and hypotonia continue to progress and usually become generalized. The deep tendon reflexes, which may be normal at admission, may diminish or disappear temporarily. The nadir of paresis and paralysis in untreated patients usually occurs within 1 to 2

FIG. 147.1 Mildly affected 7-week-old infant with botulism. Note the minimal signs, including ptosis, mildly disconjugate gaze, expressionless face, slack jaw, and neck and arm hypotonia.

BOX 147.1 Neurologic Signs Helpful in the Diagnosis of Infant Botulism

1. Take the patient to a dark room. Shine a bright light into the eye; note the quickness of pupillary constriction. Remove the light when the constriction is maximal; let the pupil dilate. Then immediately repeat with the light, continuing thus for 1 to 3 minutes. The initially brisk pupillary response may become sluggish and the pupil unable to constrict maximally. *Fatigability with repetitive muscle contraction is the clinical hallmark of botulism.*
2. Shine a bright light onto the fovea and keep it there for 1 to 3 minutes, even if the infant tries to deviate the eyes. Latent ophthalmoplegia may be elicited, purposeful efforts to avoid the light may diminish, or both may occur.
3. Place a clean fifth finger in the infant's mouth while taking care to not obstruct the airway. Note the strength and duration of the reflex sucking. The suck is weak and poorly sustained. The gag reflex strength also may be quickly checked (if the infant has not been fed recently).

Modified from Arnon SS. Infant botulism. *Annu Rev Med.* 1980;31:541–560.

weeks after admission; such patients often remain at their nadir for as long as 1 to 3 weeks before showing signs of improvement. However, once strength and tone begin to return, the improvement continues steadily and gradually over the ensuing weeks in the absence of complications (Box 147.2). In contrast, patients treated with human botulism immune globulin (BIG-IV) have a mean hospital stay of approximately 2 weeks (see Treatment).¹⁷

In the California experience, infant botulism does not have a relapsing or biphasic course and perceived “relapses” have been found, in retrospect, to be an indication of premature discontinuation of gavage feeding or respiratory support, of the onset of a complication (see Box 147.2), or of premature discharge. However, the clinical experience elsewhere with regard to relapses has been different.^{47,54,115,122} The patient is ready for discharge when gag, suck, and swallow are sufficiently strong both to protect the airway against accidental aspiration and to ensure adequacy of oral intake. Parents also may be taught to feed by gavage at home. In either situation, discharge may occur safely while head lag and constipation are still present.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSIS

When initially brought to medical attention, patients with infant botulism are often so mildly weak and hypotonic that the illness is not considered. Even today, more than 40 years after the disease first was recognized, suspected sepsis remains the most common admission diagnosis. A careful history (constipation is commonly overlooked) and physical examination (especially evaluation of cranial nerve function) usually can identify patients with infant botulism correctly and render unnecessary most additional testing for other entities typically suspected (Table 147.2). A review of entities that so closely mimicked infant botulism that BIG-IV was administered soon after admission identified spinal muscular atrophy type I, mitochondrial disorders, and a small number of other conditions as the actual diagnoses (see Table 147.2).⁵¹

The diagnosis of infant botulism is established by identification of *C. botulinum* (or, rarely, of neurotoxicogenic *C. butyricum* or *C. baratii*) organisms in the feces or enema effluent of an infant with clinical signs consistent with the paralyzing action of botulinum toxin.^{69,92,113} Extensive studies have demonstrated that *C. botulinum* is not part of the normal resident microbiome of infants or adults.^{11,61,138,139} If the fecal specimen is obtained sufficiently early in the course of the illness, it also will contain botulinum toxin. Because of the patient's constipation, an enema with sterile, nonbacteriostatic water (not saline) is often needed to obtain a fecal specimen for diagnostic examination. The mouse neutralization test remains the “gold standard” assay for detection of botulinum toxin and diagnosis of infant botulism.^{32,80} However, mass spectrometry for detection of botulinum toxins^{71,72,151} and nucleic

acid-based methodologies for detection of botulinum toxin genes^{74,89,105,132} are being increasingly applied. Laboratory diagnosis that identifies the type of toxin responsible for the illness is essential for the case to be registered as infant botulism⁷⁶ and is important for prognosis; mean hospital stay is significantly longer in untreated type A cases than in untreated type B cases (see Treatment).^{8,17} Physicians are reminded that in all states, botulism or suspected botulism (all types) is an immediately reportable illness.

Beside electromyography sometimes can be helpful in ambiguous situations, in that when a clinically weak muscle is tested, electromyography often discloses a pattern known by its acronym BSAP (*brief, small, abundant motor unit action potentials*).^{13,37,44,56,114,122,127} The edrophonium (Tensilon) test is unnecessary because congenital myasthenia gravis can be excluded by the history and because the immaturity of the infant's immune system precludes the occurrence of de novo myasthenia at this age. Likewise, Guillain-Barré syndrome that is well documented by consistently elevated CSF protein concentration is of negligible occurrence in infancy. In infant botulism the CSF protein concentration is normal unless the patient is mildly dehydrated.

TREATMENT

BIG-IV is approved in the United States as the specific therapy for infant botulism, and its use to treat patients hospitalized with suspected infant botulism constitutes current standard of care. BIG-IV was licensed following a 5-year, randomized, double-blind, placebo-controlled treatment trial in California that demonstrated its safety and efficacy.^{10,17} Use of BIG-IV reduced mean hospital stay per case from 5.7 weeks to 2.6 weeks ($P < .001$) and reduced mean hospitalization cost per case by more than \$99,000 (2015 dollars; $P < .001$).¹⁷ In a 6-year, follow-on open-label study, treatment with BIG-IV within 7 days of hospital admission reduced mean hospital stay to 2.2 weeks.¹⁷ Since licensure of BIG-IV in October 2003, its use in more than 1400 US infant botulism patients has resulted in more than 85 years of avoided hospital stay and more than \$125 million of avoided hospital costs. Treatment with BIG-IV should be started as early in the illness as possible to maximally neutralize the toxemia and should not be delayed for laboratory confirmation of the clinical diagnosis. BIG-IV may be obtained from the California Department of Public Health

TABLE 147.2 Working Differential Diagnosis of Infant Botulism

Most Common Admission Diagnoses	Inpatient Working Diagnoses	Clinical Mimics ^a	
Rule-out sepsis	Amino acid metabolic disorder	Acute disseminated encephalomyelitis	Likely resolved sepsis
Dehydration	Brain stem encephalitis	Acute transverse myelitis	Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency
Viral syndrome	Guillain-Barré syndrome	Carnitine deficiency	Miller-Fisher variant of Guillain-Barré syndrome
Pneumonia	Heavy metal poisoning (Pb, Mg, As)	Chiari malformation	Mitochondrial disorders
Idiopathic hypotonia	Hirschsprung disease	Congenital disorder of glycosylation	Nemaline rod myopathy
Failure to thrive	Hypothyroidism	Cystic fibrosis and hypovitaminosis A	Parainfluenza and macrocephaly
	Medium-chain acyl-CoA dehydrogenase deficiency	Dystonia	Parechovirus encephalitis
	Metabolic encephalopathy	Global developmental delay	Polio-like enterovirus
	Myasthenia gravis	Hemophilia A, cervical epidural hemorrhage	Polyradiculopathy
	Poliomyelitis	Human metapneumovirus pneumonia/bronchiolitis	Roseola
	Spinal muscular atrophy	Hypothyroidism	Spinal muscular atrophy
	Viral polyneuritis	Leukodystrophy	Urea cycle defect

^aPatients with conditions so indistinguishable from infant botulism at admission that they were treated with human botulism immune globulin (BIG-IV). Modified from Khouri JM, Payne JR, Arnon SS. More Clinical Mimics of Infant Botulism. *J. Pediatr.* 2017 (in press).

as a public service (i.e., not-for-profit) orphan drug (24-hour telephone: 510-231-7600; www.infantbotulism.org).

Successful management of infant botulism also depends on meticulous supportive care and the anticipation and avoidance of potentially fatal complications (see Box 147.2). Feeding and breathing generally require the most attention. At admission, patients should receive cardiac, respiratory, and transcutaneous blood gas monitoring (especially carbon dioxide pressure) until it becomes clear that paralysis is no longer progressing. An endotracheal tube is often necessary to maintain and protect the airway even if mechanical ventilation is not needed. Avoidance of nosocomially acquired *C. difficile* colitis is particularly important.^{48,119}

A third cornerstone of management is forbearance. Antibiotics should be reserved to treat secondary infections (principally pneumonia, urinary tract infection, and otitis media). Otherwise, their use may result in lysis of intraluminal *C. botulinum* with liberation of neurotoxin into the gut with subsequent absorption. This potential problem may be avoided by prompt treatment with BIG-IV because its substantial antitoxin content and long (28-day) half-life enable it to neutralize all circulating and newly absorbed toxin.

Tracheostomy is not necessary.⁴ Improved management of the airway can be accomplished by two simple positioning measures. First, to expand the thoracic cage and assist diaphragmatic function, patients should be placed in a crib with a rigid bottom mattress that can tilt the entire body to a 30-degree angle. Second, to tip the head back, and to maintain normal curvature of neck and airway, a soft cloth should be rolled to the thickness of about three fingers and placed under just the child's neck. This maneuver allows oral secretions to drain away from the trachea and into the posterior pharynx where they are most easily swallowed.

Intravenous feeding (hyperalimentation) is discouraged because of potential secondary infections and because it is unnecessary. Nasogastric or post-pyloric tube feeding works well. Mother's milk is the nutritional fluid of choice. Isolation measures or "enteric precautions" are not required, but meticulous hand washing and standard precautions are. Soiled diapers should be autoclaved because some of them will contain botulinum neurotoxin, as well as viable spores and vegetative cells of *C. botulinum*. For this reason staff with open lesions on their hands should not handle the diapers.

OUTCOME AND PROGNOSIS

Recovery from infant botulism occurs through regeneration of the toxin-poisoned terminal unmyelinated nerve endings. The newly synthesized nerve twigs then induce the formation of new motor endplates that are indistinguishable functionally and morphologically from

the original ones.^{40,42} In experimental animals and in human infants, completion of this process takes several weeks.⁴² Consequently, in the absence of hypoxic cerebral complications, full and complete recovery of strength and tone is the expected outcome. In addition, because botulinum toxin does not cross the blood-brain barrier to any functional degree, the child's intelligence and personality remain intact. Parents often need reassurance on this latter point. Reinfection with the same or a different toxin type of *C. botulinum* has not occurred. In the United States, the case-fatality ratio of hospitalized patients is less than 1%, a reflection of, and tribute to, the high quality of intensive care given to these critically ill infants.¹⁵⁰ In other countries the experience has not been as fortunate.⁷⁶

PREVENTION

At present the most important way to prevent infant botulism is not to feed honey to infants, and all major pediatric and public health agencies have endorsed this recommendation. Avoidance of untreated well water⁷⁵ and of pet terrapins and their commercial food¹²⁵ may also prevent some cases. In addition, breast-feeding may help moderate the rapidity of onset and the severity of illness.¹² Persuasive evidence that links infant botulism to the ingestion of corn or other syrups is lacking. In the pre-BIG-IV era, the patient with the most protracted illness was hospitalized in 1988 for 10 months at a cost of more than \$1.8 million (2015 dollars). Mean hospital costs for the placebo-treated patients in the 1992 to 1997 randomized clinical trial of BIG-IV were \$207,500, which were reduced in the BIG-IV group to \$108,000, a net cost savings of \$99,500 (2015 dollars).¹⁷ These economic facts combine with humanitarian considerations to make a compelling case for the prevention and effective treatment of infant botulism.

Tetanus

James D. Cherry • Myke Federman

Tetanus is caused by the anaerobic, spore-forming bacillus *Clostridium tetani*, an organism present in soil and in human and animal feces. The clinical symptoms are not caused by infection but result from a specific toxin, tetanospasmin, that is produced at the site of injury and acts primarily on the spinal cord but also on the brain, motor end plates, and autonomic nerves. The disease may appear as a local form or as a more generalized syndrome. It is characterized by tonic spasms of skeletal muscles, little or no fever, and occasional spasms of the glottis and larynx. Bilateral trismus is the most common sign. Active immunization is highly protective. Although tetanus is controlled well today in developed countries throughout the world, it remains a major cause of death in developing countries.^{6,32,30,87,92,97,132,141}

In the present era, there has been an increase in unvaccinated children due to personal belief exemptions. In 2012, two cases of tetanus in home-schooled children were noted.⁶⁶ One of those children was in the intensive care unit for 18 days and was hospitalized for approximately 2 months.

HISTORY

The first description of tetanus in recorded medical history probably was written by Hippocrates.⁶² A vivid picture of the clinical course of the disease was recorded by Aretaeus the Cappadocian in the second century,⁸ but very little of importance was added to this knowledge during the next 18 centuries. Transmissibility of tetanus was demonstrated by Carle and Rattone²⁶ in 1884. They reported that when the sciatic nerves of rabbits were injected with the contents of a human “pustule,” the characteristic disease developed in the animals in 2 to 3 days; inoculation of tissue obtained from their nervous systems into healthy rabbits produced a similar syndrome. The role of soil in the pathogenesis of tetanus was demonstrated by Nicolaier⁹⁴ in 1884; although he saw the organism, he was unable to recover it.

The bacterium responsible for the disease was identified first by Rosenbach,¹¹³ who described a bacillus containing a round terminal

Tetanospasms

Spasms

Muscle rigidity

Bilateral trismus

spore in pus obtained from a human case; tetanus developed when the purulent exudate was injected into animals. *C. tetani* was isolated by Kitasato,⁷⁰ who fulfilled Koch's postulates with it in 1889. One year later, von Behring and Kitasato¹³⁵ reported the appearance of specific antitoxin in the serum of animals given injections of the tetanus toxin produced by the organism. This finding was followed, in 1926, by the development of toxoid, injections of which produced immunity.

MICROBIOLOGY

The vegetative form of *C. tetani* is a gram-positive, spore-forming, motile, anaerobic bacillus that measures 0.3 to 0.5 μm in width and 2.0 to 2.5 μm in length; in culture, long filament-like cells develop.^{15,25,112,125,139} *C. tetani* is a strict anaerobe that grows best at 33°C to 37°C (91.4°F to 98.6°F); it can be cultured in many different routine media used for anaerobic organisms, such as thioglycolate, casein hydrolysate, and cooked meat. Enhanced growth occurs in medium supplemented with reducing substances and maintained at neutral or alkaline pH. With growth, gas with a fetid odor usually is produced.

The first step in the process of spore formation is the development of a bulge at one end of the organism; this bulge contains the spore and is responsible for the characteristic drumstick or tennis racket appearance. As sporulation progresses, the organism decreases in length and the spores are extruded. They stain poorly by the Gram method. Sporulation occurs in tissues as well as in vitro and is dependent on the composition of the medium and the temperature of the culture. Enhanced sporulation occurs in the presence of oleic acid, phosphates, 1% to 2% sodium chloride, and manganese salts.^{15,25,112} In vivo, sporulation is enhanced by lactic acid and other substances toxic to cells. Sporulation is inhibited by high and low temperatures (>41°C and <25°C [>105.8°F and <77°F]), glucose, fatty acids, and potassium salts. The metabolic activity of *C. tetani* is limited; carbohydrates and proteins are digested poorly, and the vegetative, nonsporulated forms are killed easily by heat and numerous disinfecting agents. In contrast, the spores are resistant to boiling and phenol, cresol, 1:1000 bichloride of mercury, and other disinfectants; however, they are destroyed by heating at 120°C (248°F) for 15 to 20 minutes. If not exposed to sunlight, the spores may survive in soil for months to years. They also may constitute part of the normal intestinal microflora of some horses, cows, guinea pigs, sheep, dogs, cats, rats, chickens, and humans.

Three nonpathogenic clostridia are present in soil and in human and animal feces: *Clostridium tetanomorphum*, *Clostridium tertium*, and *Clostridium tetanoides*. Diagnostic confusion may occur because they are morphologically similar to the organism responsible for tetanus. *C. tetani* is recovered much more commonly from cultivated than from virgin or uncultivated soil. Rural dwellers and people engaged in agricultural occupations have a higher rate of intestinal, skin, and oral carriage of the organism than do city dwellers. Dust and dirt from houses, streets, and operating rooms, as well as solutions of heroin used by injection drug users, have been found to be contaminated with the organism.

EPIDEMIOLOGY

Source of Exposure

The predominant reservoir of *C. tetani* is the soil; it is also part of the normal flora of the intestinal tract of animals, both herbivores and omnivores.¹¹² Intestinal spores and bacilli are shed in the feces of animals and contribute to the soil reservoir.

The worldwide morbidity and mortality attributable to tetanus is related inversely to adequate immunization with tetanus toxoid and directly to suboptimal hygiene, childbirth practices, and wound care.^{6,112} Throughout the world, tetanus has a seasonal trend; more cases occur in the summer or in "wet" seasons. Rates of illness are highest in countries that are located near the equator and have fertile soil.

Acute wounds, including relatively minor ones, are the site of most *C. tetani* infections leading to tetanus. In addition, infection may occur after parenteral drug use and surgical procedures. In many cases the source of exposure is unknown. The source of infection in neonatal tetanus is the umbilical cord or stump as a result of unsterile delivery

conditions and unhygienic cultural rituals involving the umbilical stump.^{63,64,106}

Incidence

The incidence of tetanus in the vaccine era is related inversely to the degree to which effective immunization programs have been implemented in a population.¹¹² In the early 1980s an estimated 2 million cases of tetanus occurred throughout the world, with 1 million fatal neonatal cases and 122,000 to 300,000 nonneonatal fatal cases.^{53,54}

Although neonatal tetanus is of very minor importance in developed areas of the world, it has been and still is a major cause of death in infants in developing countries.^{31,30,73,74,82,124,132,141} In 1993, an estimated 515,000 deaths worldwide were caused by neonatal tetanus.³⁰ These deaths occurred predominantly in Southeast Asia (34.2%); Africa (28.2%); the western Pacific, including China (21.4%); and the eastern Mediterranean region (15.7%). The global mortality rate in 1993 was estimated to be 4.1 per 1000 live births. The very high frequency of neonatal tetanus in these areas was related to conditions surrounding the birth of infants.⁵² Most babies were born in very unhygienic environments; delivery rarely took place in an adequate hospital. In addition, unclean instruments were used to sever the umbilical cord, rags—often contaminated with soil or feces—were used as dressings, and mud and manure were applied directly to the umbilical stump. In a study in Senegal that examined risk factors for the development of neonatal tetanus, the major source of *C. tetani* was found to be the hands of the birth attendant, and the mode of contamination of the infant was related to the method that the birth attendant and the mother used to dress the umbilical cord stump.⁷⁴ In rural Pakistan, the ritual of bundling (wrapping the baby for prolonged periods in a sheepskin cover after the application of cow dung) was a significant risk factor for the acquisition of neonatal tetanus.¹³ In a case-control study of risk factors for neonatal tetanus in Karachi, Pakistan, the following risks were identified: application of substances (e.g., mustard oil, ghee, or surma) to the umbilical cord, home delivery, and illiterate mothers.¹⁰⁶

In 2002, deaths worldwide caused by tetanus were estimated at 213,000, with approximately 180,000 occurring in neonates, and there were 15,000 to 30,000 maternal cases.¹⁴¹ Most maternal cases are the result of unclean delivery or abortion practices. In 2008, 59,000 neonatal deaths occurred as a result of tetanus.⁷³ In 2013, the World Health Organization (WHO) established that 49,000 newborns died from neonatal tetanus.¹⁴²

The reported incidence of tetanus and tetanus-related deaths in the United States from 1947 to 2008 is presented in Fig. 148.1, and the reported cases and fatal cases and their incidence are presented by age group for 1998 to 2000 in Fig. 148.2.^{34,99} From 1947 through 1976, the incidence of tetanus fell tenfold; since 1976, the continued decrease in incidence has been less than twofold. During the same period, mortality rates fell from 91% in 1947 to 44% in 1976 to 18% in 1998 to 2000.

In the period 1998 to 2000, 36% of the cases occurred in patients 60 years or older, 55% in patients aged 20 to 59 years, and only 9% in those younger than 20 years. During this period, the vaccination status was known in only 50 of the patients (38%). Of this group, eight (16%) had received three or more doses of tetanus toxoid, with the last dose being received less than 10 years before the onset of tetanus. None of these eight patients sought medical care for the injury before the onset of tetanus, and three were younger than 20 years. The outcome of the illness was available for only 18 of the 50 patients with a known immunization history, and one death occurred—in an injection drug user whose last dose of tetanus toxoid was 11 years before the onset of tetanus.

During the period 1998 to 2000, 60% of the cases occurred in males.

PATHOGENESIS

Tetanus is, by strictest definition, not a true infection. Spores introduced at a site of injury remain harmless until they are converted, after being stimulated by a variety of factors, to vegetative forms that multiply but do not produce injury to tissue or provoke an inflammatory response. The clinical syndrome is caused entirely by toxin elaborated in the area where the vegetative cells are growing. *C. tetani* produces two exotoxins:

* Per 1 million population.

FIG. 148.1 Reported incidence of tetanus and tetanus-related deaths in the United States, 1947–2000. (From Centers for Disease Control and Prevention. Tetanus surveillance: United States, 2001–2008. *MMWR Morb Mortal Wkly Rep.* 2011;60:365–369.)

FIG. 148.2 Reported tetanus cases and incidence rates by age group in the United States, 1998–2000. (From Pascual FB, McGinley EL, Zanardi LR, et al. Tetanus surveillance: United States, 1998–2000. *MMWR Surveill Summ.* 2003; 52:1–8.)

tetanolysin and tetanospasmin.¹⁰² Tetanolysin induces hemolysis but plays no role in the disease. The activity of tetanospasmin is responsible for the clinical features of the disease. This toxin has a molecular weight of 150 kDa and is activated by proteolytic cleavage into two polypeptides, a heavy (100 kDa) and a light (50 kDa) chain that are linked by a disulfide bond.²⁴ One milligram contains 6,400,000 lethal doses for mice; 0.00001 mg may kill a 20-g mouse in 2 hours. With the exception of the toxin produced by *Clostridium botulinum*, tetanospasmin currently is the most potent known poison. Humans are most susceptible to this agent and require only $\frac{1}{2500}$ and $\frac{1}{350,000}$ of the dose that is fatal for cats and chickens, respectively.

C. tetani is introduced into an area of injury as the spore, the form usually present in soil and intestinal contents. Disease does not develop until the spores are converted to the toxin-elaborating bacillus, which does not follow the simple inoculation of spores. When these spores are injected with very sharp needles into animals so that tissue is not injured but merely separated, tetanus does not develop. However, the addition of a small quantity of calcium chloride to a suspension of spores before injection leads to development of the typical disease. Such development is not caused by a specific effect of the cation on conversion

of the spore to the vegetative form of the organism but is related to the necrosis of tissue produced by it, which leads to a reduction in oxidation-reduction potential and oxygen tension, factors involved in vegetation of the spore; the same effects are produced by the presence of a foreign body, trauma, or a localized suppurative process.

The pathway by which toxin elaborated at the site at which *C. tetani* is multiplying reaches the central nervous system (CNS) has been a matter of controversy. Researchers first thought that tetanospasmin was absorbed chiefly by motor nerve endings and then traveled along axis cylinders to the anterior horn cells.¹⁰³ Symptoms of the disease were thought to appear only after the toxin had reached the nervous system, with the initial tetanic contractions occurring first in the injured extremity, then in the opposite limb, and finally, as the toxin diffused through the spinal cord, in all the muscles. A small amount of toxin was suggested to be absorbed into the lymph and carried to the bloodstream, from which it was taken up by motor nerve endings in various parts of the body.⁸⁴

Abel and associates¹ postulated that toxin reached the nervous system via the arterial circulation and suggested the following series of events. Some of the toxin diffuses from the local site of injury into adjacent

skeletal muscle and acts on neuromuscular organs to produce a state of maintained contraction—local tetanus. Some toxin also enters the lymphatics and bloodstream, from which it is taken up by specifically reactive cells in the spinal cord, medulla, and the motor end-organs of muscle.

Friedlander⁵² noted that tetanus toxin did not penetrate the blood-brain barrier and therefore questioned hematogenous transmission. This finding led researchers to focus attention on transport of tetanospasmin in nerves. Wright and coworkers¹⁴³ observed that direct injection of toxin into the vagal, facial, or hypoglossal nerves of rabbits led, within 24 hours, to the development of a syndrome characteristic of involvement of the brain stem, as indicated by the appearance of strabismus, immobility of hairs in the nasal cavity, salivation, bradycardia, and torticollis. Inoculation of the vagus nerve resulted in the successive development of these manifestations; those dependent on innervation from motor nuclei in close proximity to the nerve tended to appear early. This hypothesis is supported by observations indicating that a variety of substances, including India ink and radioactive compounds, migrate along peripheral nerves to the CNS after intraneural injection.⁴⁹ This observation, together with the demonstration by numerous investigators that toxin is present in the peripheral nerves closest to the site of inoculation, supports the concept of transport of tetanospasmin in the tissues of the nervous system.

Knowledge of the specific mechanisms involved in the absorption of tetanus toxin and its mechanisms of action on body cells is incomplete. Most of the evidence presently available indicates that some element of the peripheral nerve is involved. Whether transport occurs in the axis cylinder, the perineural space, or the lymphatics remains unsettled. Tetanus toxin is carried to the neurons of the sciatic nerve via the neurofibrillae in axis cylinders at a rate of approximately 3.35 mm/h.¹¹¹

PATHOPHYSIOLOGY

Tetanospasmin exerts its effects in four areas of the nervous system: (1) the motor end plates in skeletal muscle, (2) the spinal cord, (3) the brain, and (4) the sympathetic nervous system (in some cases).^{21-23,27,40,65,68,83,120,133,145}

Motor End Plates in Skeletal Muscle

Tetanus toxin has been noted to interfere with neuromuscular transmission. Release of acetylcholine from the nerve terminals in muscle is inhibited. The presence of tetanospasmin in the transverse and terminal sacs of the longitudinal elements of the sarcotubular system of skeletal muscles suggests that it acts by interfering with contraction coupling or with the mechanisms involved in contraction and relaxation. These phenomena probably are involved in the pathogenesis of local tetanus.

Spinal Cord

The effects of the toxin on the spinal cord are practically identical to those produced by strychnine. It does not act on reflex arcs that include only sensory and motor neurons (two-neuron or monosynaptic reflexes). However, the toxin profoundly alters the activity of the more complex polysynaptic reflexes involving interneurons, thereby leading to the inhibition of antagonists. Hyperpolarization of the membranes of neurons, a mechanism normally operating when direct inhibitory pathways are stimulated, is suppressed. The depolarization associated with excitation is not affected. Whether tetanospasmin blocks inhibitory synapses by preventing release of the inhibitory transmitter substance or by suppressing the action of this substance on the membrane of motor neurons is unknown. Selective blocking of inhibitory synapses in the CNS appears adequate to account for the primary phenomena of tetanus. Unchecked and uncoordinated excitatory impulses multiply and traverse reflex pathways to produce the characteristic tetanic spasms of muscles.

Brain

Some investigators have suggested that the action of tetanospasmin on the brain may be responsible for the typical seizures of tetanus.²¹ This hypothesis is supported, in part, by the observation that cerebral gangliosides fix the toxin. The antidromic inhibition of evoked cortical

activity is decreased. The effects of tetanospasmin on the brain are the same as those on the spinal cord, as well as those that occur after exposure to strychnine.

Sympathetic Nervous System

Manifestations indicating dysfunction of the sympathetic nervous system have been observed in some patients with tetanus. Signs and symptoms include profuse sweating, peripheral vasoconstriction, labile hypertension, cardiac arrhythmias, tachycardia, increased output of carbon dioxide, elevated urinary concentration of catecholamines, and hypotension late in the course of the disease.

CLINICAL MANIFESTATIONS

Although it may be as short as 1 day or as long as several months, the incubation period of tetanus usually is 3 to 21 days. A direct relationship may exist between the distance of the site of invasion by *C. tetani* from the CNS and the length of the interval between injury and the onset of disease; the greater the distance between the local area and the CNS, the longer, in general, the incubation period. Sustained or separate, repeated tonic spasms of isolated or multiple muscles are the characteristic clinical feature of the disease. Tetanus may appear in two forms: local and generalized.

Local Tetanus

The occurrence of local tetanus most likely is more common than recognized. Although local tetanus is thought to occur infrequently, it probably is so because it may be uncommon as an isolated syndrome or because by the time that diffuse involvement has occurred, the spasms in the muscles in the area of the site of entry of the organism cannot be separated from the generalized spasms. Local manifestations frequently precede development of the generalized disorder. The characteristic abnormality in local tetanus is unyielding, persistent, painful rigidity of the group of muscles that lie in close proximity to the site at which *C. tetani* was introduced. Local tetanus often is present when a dose of antitoxin has been given that is adequate to inactivate circulating toxin but insufficient to neutralize what has accumulated at the site of injury. Symptoms may persist for several weeks or months and finally disappear without leaving any residua.^{85,107} Local tetanus may be the only manifestation, usually is mild, and has a fatality rate of approximately 1%.

Cephalic tetanus is a variant of local tetanus. It generally occurs after the introduction of *C. tetani* in the course of injuries to the scalp, eye, face, ear, or neck; in conjunction with chronic otitis media; and rarely, after tonsillectomy.^{5,10} Insect bites on the face or head, especially if secondarily infected by pyogenic organisms, also may serve as portals of entry for the organism. The incubation period of this syndrome is short, frequently no more than 1 to 2 days. The principal distinctive clinical features are palsies of cranial nerves III, IV, VII, IX, X, and XII; they may be involved singly or in any combination. Dysfunction may persist for days or many months. In general, the prognosis for survival is poor. However, if death does not intervene, complete recovery without residual neurologic dysfunction is the rule. In some, but not all, instances, generalized tetanus may develop during the course of the cephalic form of the disease.

Generalized Tetanus

Generalized tetanus is the most common manifestation of the disease.^{109,137} Despite the general impression that inoculation of the organism is associated most frequently with deep penetrating injury, the portal of entry in approximately 80% of cases is an insignificant wound.¹⁰³ Burns, injuries induced by blank cartridges, deep punctures, furunculosis, dental extraction, embedded splinters, decubitus ulcers, hypodermic injections, and compound fractures complicated by chronic active osteomyelitis are typical situations in which tetanus may develop because the environment in the tissues is optimal (decrease in oxidation-reduction potential and tension of oxygen) for conversion of spores to the toxin-producing vegetative organisms. Iatrogenic disease has occurred after the use of smallpox vaccine and surgical sutures contaminated with the spores of *C. tetani*. It also has occurred as a postoperative complication in patients exposed to the organisms present in the dust in operating rooms.^{105,108,119}

Very minor injuries, such as penetration by “clean” sewing needles and bites by chiggers, bees, and scorpions, have been recorded as portals of entry. Tetanus also has occurred after induced abortion, usually one performed under poor asepsis.

The initial manifestation in more than 50% of cases of generalized tetanus is trismus; it may be unilateral early in the disease but becomes bilateral within a short time. In some cases, it may be absent during the entire course of the illness or appear only after other abnormalities have become evident. In some instances, the only symptoms and signs may be irritability, restlessness, stiffness of the neck, difficulty swallowing, and rigidity of the abdominal or thoracic muscles; these symptoms may be present singly or in various combinations. The diagnostic importance of trismus cannot be overemphasized, despite the fact that it may be associated with numerous disorders unrelated to tetanus. Among these disorders are postmeasles encephalitis, trichinosis, suppurative and other types of parotitis, tender cervical lymphadenopathy, infected impacted upper molar teeth, and exposure to phenothiazine drugs.

As the activity of tetanospasmin persists, groups of muscles other than the masseters may become involved, including tonic spasms of the jaw, neck, back, and abdomen. Unrelenting trismus leads to the development of a characteristic facial expression, the sardonic smile (*risus sardonius*). The abdominal and spinal muscles may become rigid. Intense and sustained contraction of the muscles of the chest and back results in persistent opisthotonos; in young children, this condition may be so severe that the youngster lies on one side with the soles of the feet resting on top of the head.

Generalized seizures, or tetanospasms, are unique in their appearance and peculiar to this disease. Characteristically, a sudden burst of tonic contractions of all groups of muscles occurs and leads to the development of opisthotonos, flexion and abduction of the arms, clenching of the fists on the chest, and extension of the legs. Pain in the spastic muscles usually is severe. Glottal and laryngeal spasm with the chest in the position of full inspiration may develop in some patients. During such an episode, the face becomes florid, the neck veins are distended markedly, and cyanosis develops. The features of this syndrome are consistent with an intense and sustained Valsalva maneuver; unless the tonic contraction of the glottis and larynx subsides or a tracheostomy is performed, death results. Dysphagia and hydrophobia may develop as isolated phenomena in the absence of a generalized tetanospasm. Dysuria or urinary retention also may occur.

Autonomic nervous system dysfunction commonly occurs in tetanus.^{76,127,136} Manifestations include labile or persistent hypertension or hypotension, persistent sinus tachycardia, tachyarrhythmia or bradycardia alternating with tachycardia, and profuse sweating.

Electroencephalographic studies of patients have indicated involvement of the brain. Of 106 patients studied by Luisto,⁷⁸ 76% were found to have abnormal electroencephalograms. When patients of the same age and sex who had not had tetanus were compared with 40 individuals who had contracted the disease 7 years earlier, the latter were found to have more muscle fatigue and cramps; difficulty in speech, balance, and memory; and more peripheral paresis, muscular atrophy, decreased or absent tendon reflexes, and impaired mental capacity.⁶⁹

The generalized seizures of tetanus often are triggered by very slight external stimuli, such as a light breeze, talking, a bump on the bed, or slight touching of the patient. The intense work generated by sustained or frequently repeated tetanospasms often leads to increases in body temperature of 1°C to 3°C (33.8°F to 37.4°F) or more.

The intense suffering of patients with the generalized tonic seizures of tetanus and the total frustration of the physician, who in ancient times had to stand by helplessly, unable to alter the course of the disease, were described best by Aretaeus⁸ in the second century BCE; no better description has ever appeared:

An inhuman calamity! An unseemly sight! A spectacle painful even to the beholder, an incurable malady! Owing to the distortion, not to be recognized by the dearest friends; and hence the prayers of the spectators, which formerly would have been reckoned not pious, now becomes good, that the patient may depart from life, or being a deliverance from the pains and unseemly evils attendant on it. But neither can the physician, though present and looking on, furnish any assistance, as regards life, relief from pain or from deformity. For if he should wish to straighten the limbs, he can do so only

by cutting and breaking those of a living man. With them, then, who are overpowered by this disease, he can merely sympathize. This is the great misfortune of the physician.

Injection Drug Users

When generalized tetanus develops in injection drug users, many of the clinical features differ from those present in people who do not use drugs.⁷⁵ Among such features are much higher levels of fever; absence of trismus at onset and throughout the course of the disease or its appearance at some time after other manifestations have been present; marked stiffness of the neck and back, which in the absence of trismus may be confused with meningitis (the normal cerebrospinal fluid in patients with tetanus excludes this possibility); and early onset of coma. Prophylaxis is less effective in injection drug users than in non-injection drug users. The fatality rate approaches 100%.

Neonatal Tetanus

Neonatal tetanus usually begins 3 to 14 days after birth and is characterized by poor sucking and excessive crying.^{52,137} Manifestations include trismus, difficulty swallowing, other tetanic spasms, and, frequently, marked opisthotonos.

A study by Salimpour¹¹⁵ of the causes of death in patients with neonatal tetanus indicated pulmonary disease to be most common. Bronchopneumonia or hemorrhage in the lungs (or both) was the most frequent finding at autopsy. Among the nonpulmonary disorders responsible for a fatal outcome were hepatitis, omphalitis, cerebral hemorrhage, thrombosis, and rupture of the renal vein. As has been noted not only in infants but also in older children and adults with tetanus, any gross or histologic abnormalities are very uncommon findings. The complications described by Salimpour,¹¹⁵ especially those involving the lungs, probably are related to aspiration associated with the laryngoglottal spasm characteristic of the disease. Newborns who survived tetanus in rural Kenya often had evidence of brain damage.¹¹ Indicators of a poor prognosis for neonates include age younger than 10 days when admitted to the hospital, symptoms of less than 5 days' duration, and the presence of *risus sardonius* and fever.⁸⁰

DIAGNOSIS

Differential Diagnosis

The differential diagnosis depends on the major clinical manifestations of the illness.¹¹² Cephalic tetanus may be confused with Bell palsy, trigeminal neuritis, and encephalitis, whereas generalized tetanus can be confused with rabies, strychnine poisoning, and phenothiazine reactions. An 11-year-old boy with neuromyotonia (Isaac syndrome) was diagnosed as having tetanus.⁹⁸ Trismus can result from dental problems, tonsillitis, peritonsillar abscess, temporomandibular joint dysfunction, and parotitis. Tetany caused by hypocalcemia or hyperventilation should be considered as well.

Specific Diagnosis

The diagnosis of tetanus is established on the basis of the history of an injury, particularly one in which either soil or fecal material has been introduced. In a small number of cases, especially those in which a relatively long incubation period has occurred, the site of entry of the organism may be healed and undetectable. In a review of 130 cases that occurred in the United States between 1998 and 2000, 94 (72%) were related to an acute injury⁹⁹—47 puncture wounds, 31 lacerations, and eight abrasions. In 34 cases not involving an acute injury, the following associations were noted: abscess, seven cases; ulcer, seven cases; gangrene, two cases; cellulitis, one case; gingivitis, three cases; and other infections, two cases. In 12 cases, no injury or other source location was identified. One of the 130 patients was a neonate, and 18 of the nonacute injury cases occurred in patients with a history of injection drug use. Laboratory studies are of little help. Peripheral leukocytosis may or may not be present. The characteristic gram-positive rods, some of which may contain subterminal spores, may be seen occasionally in stained material obtained from the wound that has served as the portal of entry. Anaerobic cultures of exudate or necrotic tissue may grow typical sporulated rods and vegetative forms, but the yield of positive findings tends to be low.³⁸

Low or undetectable levels of serum antitoxin at the time of onset of the illness are supportive of the diagnosis, but, occasionally, serum antitoxin is present.¹¹² Rises in antitoxin titer occur uncommonly after infection, so the use of paired sera for retrospective diagnosis generally is not helpful; in addition, this form of serologic diagnosis is not possible when therapy included active immunization. In selected cases, electrophysiologic studies of the masseter muscle may be helpful.¹² A characteristic absence or shortening of the silent period occurs as a result of failure of Renshaw cell inhibition; exaggerated F responses indicating hyperexcitability also may be noted.

TREATMENT

Management of generalized tetanus is directed at the following goals:

1. Neutralization of toxin still present in the blood before it comes in contact with the nervous system. Neutralization is accomplished by the administration of antitoxin as soon as the possibility of the disease is suspected or confirmed.^{7,15} However, no acceptable evidence has shown that toxin can be inactivated by antitoxin once the toxin is fixed to tissues. In fact, the effectiveness of even large doses of antitoxin in reducing the fatality rate has been questioned.
2. Surgical removal of the site of entry of the organism, when possible, to eliminate the “factory” in which tetanospasmin is being produced. Omphalectomy has been performed with good results in children with neonatal tetanus.⁴¹ Hysterectomy has been recommended when the disease has complicated induced and often septic abortions; however, patients in whom the infected uterus is not removed occasionally may survive. When the surgical procedure may be mutilating, as is the case with lesions on the face, it should not be performed.
3. Constant and meticulous intensive care unit monitoring and nursing care, with particular attention to fluid, electrolyte, and caloric balance because these frequently are abnormal, especially in patients with high temperature and repeated seizures, as well as in those unable to take food or liquids because of severe trismus, dysphagia, or hydrophobia.
4. Management of muscle spasm and autonomic instability.

The slightest external stimulus may precipitate potentially lethal seizures in persons with diffuse disease. For this reason, all therapeutic and other manipulations should be coordinated and carefully scheduled so that the risk for producing a tetanospasm is reduced to a minimum. All maneuvers are performed best after patients have received optimal sedation and relaxation. A quiet, darkened room in which the light is subdued and the doors padded, removed as far as possible from the mainstream of hospital traffic, is ideal, but at the same time the patient requires constant monitoring and observation in an intensive care environment.

The antitoxin of choice for the treatment of tetanus is human tetanus immune globulin (TIG) at a dose of 3000 to 6000 U intramuscularly; a second dose does not appear to be necessary. When TIG is not available, equine antitoxin (EA) may be used, but it should be avoided if at all possible. The dose of EA is 100,000 U; half is injected intramuscularly after appropriate tests to rule out sensitivity to horse serum have been performed. If EA is well tolerated, the remainder is given slowly intravenously. Patients sensitized to horse serum must be desensitized. An intramuscular injection of 80,000 units of EA produces maximal concentrations of antibody in the blood in 48 to 72 hours; very good levels may be maintained for 7 days.^{57,130,131} Intravenous administration of the same dose yields concentrations of 40 U or more of antitoxin per milliliter of serum after 6 hours; it may persist for approximately 48 hours. Essentially no difference in circulating quantities of antitoxin exists 7 days after it is given by either route. Local instillation of antitoxin around the known or suspected wound may be of value if excision cannot be performed; it also has been recommended before surgical removal of the injured area.

Intravenous immune globulin (IVIG) contains antibodies to tetanus toxin.⁷ The Committee of Infectious Diseases of the American Academy of Pediatrics suggests using IVIG in a dose of 200 to 400 mg/kg if TIG is not available.

Although reports^{93,94} have documented that intrathecal administration of antitetanus serum did not improve the rate of survival in neonatal

tetanus, the results of a study by Mongi and colleagues⁹⁰ led them to recommend this form of therapy. They found that intrathecal serotherapy may be of great value in the management of tetanus. Their experience indicated that the death rate from this disease in patients given intrathecal therapy was 45%; in those who did not receive this agent, it was 82%.² In a controlled trial in Brazil involving 120 adolescents and adults, 58 patients received TIG intrathecally and intramuscularly and 62 received TIG only by the intramuscular route.⁸⁶ The patients who received intrathecal and intramuscular treatment had better clinical progression than did those who were treated by only the intramuscular route. Two smaller pediatric-specific reports also suggest a morbidity and mortality benefit from intrathecal versus intramuscular administration of TIG or antitoxin. Ahmad and colleagues demonstrated a reduction in mortality and hospital stay in 35 neonates treated with intrathecal TIG compared to 35 neonates who received antitetanus serum via the intramuscular route.³ A retrospective analysis by Geeta and colleagues of 66 children who received intrathecal TIG also suggested a morbidity and mortality reduction compared to intramuscular treatment alone.⁵⁵

Two meta-analyses have been performed in an effort to establish the true benefit of intrathecal therapy, but unfortunately, they found conflicting results. The results of one meta-analysis led Abrutyn and Berlin² to conclude that intrathecal therapy with either EA or TIG is not of proved benefit and, therefore, should be given only during well-designed, controlled therapeutic trials.

A meta-analysis that involved 942 patients in 12 trials was reported.⁶⁷ In this analysis, the overall relative risk for mortality with intrathecal (antitetanus serum or TIG) versus intramuscular therapy was 0.71 (95% confidence interval, 0.62–0.81). Subcategory analyses for both adults and neonates and for high- and low-dose intrathecal therapy also indicated the beneficial effect of intrathecal therapy.

Penicillin kills the vegetative forms of *C. tetani*. Parenteral administration of penicillin G, 100,000 U/kg/day intravenously every 6 hours for 10 days, has been recommended in the past in all cases of tetanus. Observations have suggested that penicillin may act as an agonist to tetanospasmin by inhibiting the release of γ -aminobutyric acid (GABA).¹¹² Because of this possibility and the results of a controlled study in Indonesia, metronidazole has become the antimicrobial treatment of choice.⁴⁷ The metronidazole dosage is 30 mg/kg/day intravenously every 6 hours after an initial dose of 15 mg/kg. The usual duration of therapy is 10 to 14 days.

The spasticity and seizures of tetanus are caused by exaggerated reflex responses to afferent stimuli as a result of suppression of balancing central inhibition. Several classes of drugs that act at different sites along the reflex pathway are useful for control of these manifestations. Among them are hypnotics and sedatives, which reduce sensory input and generalized excitability; general anesthetics, which produce broad depression of the CNS; centrally acting muscle relaxants or spinal depressants, which lower reflex activity and decrease motor output from the spinal cord; and neuromuscular blocking agents, which inhibit the transmission of excess motor nerve activity to effector muscles.

Historically many different drugs have been used for the patient with tetanus. The use of diazepam was first reported in *The Lancet* in 1965, shortly after the drug was introduced clinically.⁶¹ Since then the benzodiazepines have become the preferred drugs for the spasms and rigidity associated with tetanus.^{39,96,126,134} They also have the advantage of being potent anticonvulsants and sedative hypnotic agents. Additionally, they are GABA agonists, perhaps partially overcoming the effect of tetanospasmin interfering with the normally inhibitory effect of GABA.¹³³ Diazepam (Valium) and lorazepam (Ativan) have been the most frequently used benzodiazepines for tetanus. Lorazepam has a somewhat longer half-life and may be preferred for this reason. Very large total daily doses (500 mg) of diazepam or lorazepam (200 mg) may be required.¹²⁰ Both drugs are formulated in propylene glycol solution for intravenous dosage, and the large doses required may result in significant propylene glycol toxicity, including a metabolic acidosis. For this reason, an enteral preparation that is free of propylene glycol should be given enterally if at all possible.¹⁷

Midazolam (Versed) is a short-acting benzodiazepine that is soluble in water and thus does not include propylene glycol in its parenteral formulation. Because of its short half-life, it should be administered as

a continuous infusion and an initial infusion dose of 0.1 to 0.3 mg/kg per hour may be required. The benzodiazepines all induce tachyphylaxis and will require escalation of the dosage with time. The dosage should be titrated to prevent tetanic spasms and provide adequate sedation instead of being a specified dose. To avoid withdrawal symptoms after long-term use, the benzodiazepines should be tapered over the course of several weeks.

Magnesium sulfate has been advocated by some authors as first-line therapy for tetanus.^{9,104,129} Magnesium was first reported as a therapy for tetanus, given intrathecally, more than 100 years ago.¹⁶ Magnesium is a muscle relaxant and has been well tolerated at high doses in the obstetric population. In addition, magnesium reduces catecholamine release and lowers heart rate and vascular tone, stabilizing some of the effects of autonomic instability seen in tetanus. The largest trial of magnesium therapy for severe tetanus was reported in *The Lancet*.¹²⁹ This was a randomized, double-blind, placebo-controlled trial of 256 Vietnamese patients over the age of 15 years. Magnesium was given as a loading dose of 40 mg/kg followed by an intravenous infusion titrated to maintain serum levels of 2 to 4 mmol/L. There was no difference in the requirement for mechanical ventilation, although the patients receiving magnesium required less benzodiazepine and neuromuscular blockade and also were less likely to require treatment for cardiovascular instability. A smaller, less well-controlled clinical trial of magnesium has reported a decreased incidence of the need for mechanical ventilation.¹²¹ Case reports in the pediatric population are somewhat limited,^{28,104} although both reports advocate the use of magnesium as part of the therapeutic regimen for tetanus.

If benzodiazepines and magnesium are unable to control the spasms and rigidity associated with tetanus, intrathecal baclofen should be considered. Baclofen is a GABA receptor agonist that directly stimulates the postsynaptic GABA β receptors on synapses blocked by tetanus toxin, thereby restoring physiologic inhibition of the α motor neuron. Numerous centers have described the efficacy of intrathecal baclofen for treating tetanus, although its safety and efficacy have not been established in children younger than 4 years.^{18,44,45,117} When magnesium, benzodiazepines and intrathecal baclofen are unable to control the spasms and rigidity associated with tetanus, neuromuscular blockade is indicated. Although succinylcholine has been used in the past,³¹ newer agents have supplanted it. Additionally, theoretical reasons provide the basis to avoid the use of succinylcholine. With functional denervation of the motor end plate in neuromuscular junctions directly affected by tetanospasmin, succinylcholine may result in exaggerated release of potassium and hyperkalemia. This condition has been associated with cardiac arrhythmias and death in other denervating conditions. For this reason, nondepolarizing agents should be used. Potential agents include pancuronium, vecuronium, atracurium, cisatracurium, rocuronium, and pipecuronium—the agent of choice in a large tetanus treatment center in Vietnam.¹²⁹

Neuromuscular blocking drugs should be used only by physicians experienced in their use in a critical care environment, typically anesthesiologists or intensivists.⁷² Although neuromuscular blockers formerly were used at low doses to preserve diaphragmatic function and spontaneous respiration, current thought is that they should be administered in conjunction with tracheostomy or endotracheal intubation and ventilatory support. Remembering that neuromuscular blocking drugs have no effect on cortical function and have no sedative effect is critical. The benzodiazepines are good sedatives and have a significant amnestic effect. They are not, however, analgesics, and if pain is present (such as from previous muscle spasms), morphine sulfate is an effective analgesic. It also may be helpful in treating sympathetic hyperactivity. If sympathetic overactivity remains problematic, a combined α - and β -receptor blocker such as labetalol should be used. The use of a β -blocker such as propranolol alone should be avoided because the unopposed α -mediated vasoconstriction could lead to significant hypertension. Several alternative therapies have been suggested, but their use is not widespread, so it is difficult to draw conclusions regarding their efficacy. Clonidine and dexmedetomidine, both α_2 -adrenoreceptor agonists, have shown potential benefit in controlling both muscle spasm and hemodynamic instability.^{56,58,88} A combination of epidural bupivacaine and sufentanil has been used by some physicians to treat the sympathetic overactivity.¹¹ Finally, isolated case reports have shown success with

dantrolene, ketamine, and propofol in combination with the agents described earlier.^{14,19,36,88,95}

The management approach to a patient with tetanus spasms or rigidity should be one of escalation of therapy based on need. Benzodiazepines should be administered initially, with high doses often being required. If the benzodiazepines are not effective, infusion of magnesium to decrease muscle spasms and cardiovascular instability should be considered.¹²⁹ If control of the spasms or rigidity is still not achieved, intrathecal baclofen may be used.^{44,45} If these therapies are inadequate or result in airway compromise or inadequate ventilation, endotracheal intubation should be performed with a nondepolarizing neuromuscular blocking agent.

Sixty-six percent of 103 children aged 1 to 12 years with severe tetanus studied by Wesley and Pather¹³⁸ required management with total muscle paralysis and intermittent positive-pressure ventilation. The death rate in this group was 14.5%.

PROGNOSIS

The average fatality rate associated with tetanus ranges from 25% to 70%, but mortality rates can be reduced to 10% to 30% with modern intensive care.^{110,112} The risk for death occurring in patients with tetanus neonatorum is particularly high; it was reported to be 99.5% in a group of 5794 infants in 1930.⁶² With modern treatment and high-intensity supportive care, the mortality rate associated with neonatal tetanus can be reduced to approximately 25%.¹¹² Injection drug users are highly susceptible to the development of very severe disease and are likely to die.^{69,75}

A variety of other factors play an important role in determining the outcome of tetanus.^{60,128} Patients in the second and third decades of life have a higher rate of recovery than the elderly. An inverse relationship exists between the length of the incubation period and risk, as first pointed out by Hippocrates. The risk for death is approximately 58% when the interval between injury and the onset of tetanus is 2 to 10 days. When the interval is 11 to 22 days or longer, fatality rates have been 35% to 17%, respectively. A relationship also appears to exist between the period elapsing from the time of appearance of the first signs of tetanus and development of the first seizure or maximal intensity of the disease; the shorter this interval, the poorer the prognosis.³⁸

The clinical form of tetanus also influences the outcome.⁷⁷ Cephalic tetanus and tetanus neonatorum are associated with the highest incidence of death. In contrast, local tetanus, unless complicated by development of the generalized syndrome, has an excellent prognosis. Early administration of prophylactic antitoxin markedly increases the frequency of survival.

Cause of Death

Because the clinical course of tetanus may be prolonged and the therapy used is complex and potentially dangerous, the cause of death often is not clear. Animals may die after the injection of toxin without any recognizable signs of the disease appearing.⁵⁰ Studies in parabiotic rats suggest that tetanospasmin exerts a lethal effect on the respiratory center.¹¹⁸ Involvement of the medulla has been observed in experimental animals and humans, in whom episodes of respiratory failure, often in the absence of seizures, have been described.^{72,143} The action of the toxin on brain tissue has been postulated to be the cause of hyperpyrexia, tachycardia, hypotension, bulbar palsy, and cardiac arrest.⁹¹ Myocardial damage also may occur, and both histologic and electrocardiographic abnormalities have been described.¹⁰¹

Death may occur during a seizure, but the specific mechanisms involved are not clear in all cases. Laryngospasm and disturbances in electrolyte balance may play important roles. Pneumonia complicating aspiration, induced by an inability to swallow and oversedation, occurs commonly. It may be directly responsible for death or may contribute to a fatal outcome by increasing the degree of anoxia of the respiratory center.

PREVENTION

As noted in Fig. 148.1, tetanus in the United States has decreased dramatically, and this decline can be attributed to routine universal use of

tetanus toxoid and improved wound management, including the use of tetanus prophylaxis in emergency departments.

Active Immunization

For complete information regarding tetanus immunization, the reader is referred to the most recent recommendations of the Advisory Committee on Immunization Practices of the US Public Health Service,^{29,30,33} the recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics,⁷ and product information from vaccine manufacturers.

In the United States, primary immunization against tetanus is performed in conjunction with immunization against diphtheria and pertussis in the form of diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed (DTaP). The schedule involves an initial series of three doses of vaccine at 2, 4, and 6 months of age; a reinforcing dose at 12 to 18 months of age; and a booster dose at 4 to 6 years of age. After the initial series, additional booster doses of adult-type diphtheria and tetanus toxoids adsorbed (Td) are recommended at 10-year intervals.^{41,43} In 2005, two adult-type diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed (Tdap) were approved for use in the United States.^{32,33} In adolescents and adults, Tdap should be the routine vaccine. At present, Tdap vaccines are FDA approved for only one dose, but our opinion is that an every-10-year boosting schedule with Tdap rather than Td will maintain protective antitoxin levels and be less confusing for the physician. It is anticipated that a boosting schedule of Tdap will be similar to that recommended for Td (every 10 years). The minimal serum level of antitoxin needed for protection is 0.01 IU/mL.^{42,79,80,122} After the initial three-dose series, the reinforcing dose, and the booster dose, levels of antitoxin 100- to 1000-fold higher than 0.01 IU/mL are attained, and levels higher than 0.01 IU/mL persist in nearly all vaccinees until the scheduled subsequent dose.

Although protection against tetanus by immunization is long-lasting in most children and adults, some immunocompromised children and adults may need more frequent booster doses.^{37,71,87,89}

Tetanus Prophylaxis in Wound Management

Antimicrobial prophylaxis against tetanus is neither practical nor useful in managing wounds.^{20,144} Cleaning of the wound, debridement when indicated, and proper immunization are important factors. The need for tetanus toxoid (active immunization), with or without TIG (passive immunization), depends on both the condition of the wound and the patient's vaccination history (Table 148.1).^{7,29,35} Rarely has tetanus occurred in persons with documentation of having received a primary series of toxoid injections.

A thorough attempt must be made to determine whether a patient has completed primary vaccination. Patients with unknown or uncertain previous vaccination histories should be considered to have had no previous tetanus toxoid doses. Patients who have not completed a primary series may require tetanus toxoid and passive immunization at the time of wound cleaning and debridement (see Table 148.1).

The evidence available indicates that complete primary vaccination with tetanus toxoid provides long-lasting protection for 10 or more years in most recipients. Consequently, after complete primary tetanus vaccination, boosters—even for wound management—need to be given only every 10 years when wounds are minor and uncontaminated. For other wounds, a booster is appropriate if the patient has not received tetanus toxoid within the preceding 5 years.¹⁰⁰ Antitoxin antibodies develop rapidly in persons who have received at least two doses of tetanus toxoid.

Tdap is the preferred preparation for active tetanus immunization in the wound management of patients aged 7 years or older. Because a large proportion of adults are susceptible, this plan enhances diphtheria protection. Thus, by taking advantage of acute health care visits, such as for wound management, some patients can be protected who otherwise would remain susceptible. For routine wound management in children younger than 7 years of age who are not vaccinated adequately, DTaP should be used instead of Td. Td may be used if there is a valid contradiction to pertussis vaccine. For patients of all ages who are inadequately vaccinated, completion of primary vaccination at the time of discharge or at follow-up visits should be ensured. Presently, Tdap rather than Td is recommended for wound management in adolescents and adults.^{32,33}

If passive immunization is needed, human TIG is the product of choice. It provides protection longer than that of antitoxin of animal origin and causes fewer adverse reactions.^{81,114,123} The TIG prophylactic dose currently recommended for wounds of average severity is 250 U intramuscularly. When tetanus toxoid and TIG are given concurrently, separate syringes and separate sites should be used. If TIG is not available, intravenous immune globulin should be used.

Neonatal Tetanus

Several approaches have been taken to reduce the incidence and fatality rate of neonatal tetanus in developing areas of the world. Among these approaches are (1) educating pregnant women concerning the danger of using contaminated materials for cutting the umbilical cord and covering the stump, (2) training midwives in the application of modern techniques of obstetric asepsis, (3) developing hospitals in which babies are born under strict asepsis, and (4) immunizing all women of child-bearing age or, if such immunization is not possible, all who are pregnant. Studies performed by the WHO have demonstrated

TABLE 148.1 Summary Guide to Tetanus Prophylaxis in Routine Wound Management

History of Adsorbed Tetanus Toxoid (Doses)	CLEAN, MINOR WOUNDS		ALL OTHER WOUNDS ^a	
	DTaP, Tdap, or Td ^b	TIG ^c	DTaP, Tdap, or Td ^b	TIG ^c
Unknown or <3	Yes	No	Yes	Yes
≥3 ^d	No if <10 y since last tetanus-containing vaccine dose Yes if ≥10 y since last tetanus-containing vaccine dose	No	No ^e if <5 y since last tetanus-containing vaccine dose Yes if ≥5 y since last tetanus-containing vaccine dose	No

DTaP, Diphtheria and tetanus toxoids and acellular pertussis vaccine; Td, adult-type diphtheria and tetanus toxoids vaccine; Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; TIG, tetanus immune globulin (human).

^aSuch as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, or frostbite.

^bFor children <7 years, DTaP (unless there is a pertussis contraindication vaccine) is preferred to tetanus toxoid alone. For persons ≥7 years, Tdap is preferred to Td alone.

^cIntravenous immune globulin should be used when TIG is not available.

^dIf only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.

^eMore frequent boosters are not needed and can accentuate adverse effects.

that such immunization is practical and leads to an appreciable reduction in the incidence of neonatal tetanus.^{48,47,46,124,132,141} Babies born to mothers who have been immunized during pregnancy have adequate levels of circulating antibody and are protected against acquiring the disease. The level of protective antibody in newborns and the magnitude of the transfer rate of passive immunity to tetanus depend directly on the level of tetanus antitoxin in maternal serum. Mothers who had tetanus antitoxin levels of 1.28 IU/mL or greater could transfer protection to almost all the newborns (97–100%), irrespective of the doses of tetanus toxoid administered. Mothers who had received two doses of tetanus toxoid during pregnancy not only conferred good protection but also transferred high antitoxin levels to their newborns.¹¹⁶

In 1989, the WHO adopted a resolution to eliminate neonatal tetanus worldwide,^{120,121} and in 1990, the World Summit for Children issued a declaration for global elimination of neonatal tetanus by the end of 1995.^{30,140} In 1993, the WHO's goal was defined as elimination of neonatal tetanus as a public health problem by reducing its case incidence to less than one per 1000 live births for all health districts.⁵⁹

From 1989 to 1993, the rate of vaccination coverage with two or more doses of tetanus toxoid administered to pregnant women in areas at risk increased from 27% to 45%. To achieve and maintain elimination of neonatal tetanus, 80% or more of infants need to be protected at birth through vaccination of their mothers with at least two doses of tetanus toxoid or through clean delivery and cord-care practices.⁵⁹ Considerable progress has been made in the reduction of maternal and neonatal tetanus, but the goal to reduce the rate of neonatal tetanus cases to less than one per 1000 live births in all geographic areas has not been achieved.¹³² In 2003, 57 countries still remained in which neonatal tetanus had not been eliminated in all districts.

Actinomycosis

Suzanne Whitworth • Morgan A. Pence • Richard F. Jacobs

Human actinomycosis is a clinical illness with typical histologic findings that is caused by a variety of pathogens. Actinomycetes are a group of aerobic and anaerobic bacteria in the order Actinomycetales. The name *actinomycosis* means “ray fungus,” and the organisms may resemble fungi because of their filamentous appearance.⁶⁶ Actinomycosis is often polymicrobial, and *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans* is frequently a co-pathogen. It is endogenous worldwide, with sporadic cases reported annually. Occurrence of the disease is unrelated to age, sex, season, or occupation, although it is an uncommon event in the pediatric population. These organisms have the ability to spread locally without regard to fascial planes or other anatomic barriers. Actinomycosis is characterized by localized swelling with suppuration, abscess formation, and draining sinuses. The abscesses have fibrous walls and are filled with pus and characteristic sulfur granules. The three most common types of actinomycosis are oral/cervicofacial, abdominal/pelvic, and pulmonary. However, involvement of the liver,

female reproductive tract, and brain has been described. Definitive diagnosis of the infection rests on isolation of the organism from pus or identification of sulfur granules on histopathologic sections of biopsy material. Adequate treatment generally consists of surgical removal of the lesion, prolonged antibiotic therapy, or a combination of both.

MICROBIOLOGY

The clinical entity of actinomycosis has historically been attributed to species of the genera *Actinomyces* and *Propionibacteriu*. Over time and with improved methods of detection this definition has broadened to include other genera, including *Actinobaculum*, *Cellulomonas*, and *Trueparella*. Other actinomycosis-related genera include *Actinotignum* and *Varibaculum*.²⁶ Human actinomycosis most often is caused by *Actinomyces israelii*, although over 20 species of *Actinomyces* are reported to cause human disease, including

more commonly, *Actinomyces gerencseriae*, *Actinomyces naeslundii*, *Actinomyces viscosus*, *Actinomyces odontolyticus*, *Actinomyces meyeri*, *Actinomyces radidentis*, *Actinomyces neuii*, *Actinomyces radingae*, *Actinomyces turicensis*, and *Actinomyces graevenitzi*.^{22,54} *Propionibacterium propionicum* is the only species in the *Propionibacterium* genus that is a cause of human actinomycosis.

These bacteria are irregular, non-spore-forming, non-acid-fast, non-motile, gram-positive rods. They grow in most rich culture media and have various oxygen requirements. For example, *A. israelii* requires anaerobic conditions for growth. *A. viscosus*, however, grows in an aerobic environment with carbon dioxide. These species ferment carbohydrates as their source of energy for growth.¹⁸ These organisms are now firmly classified as prokaryotic bacteria, although they originally were thought to be fungi because of the mycelial appearance of the organisms in sulfur granules and their branching morphology. They are also members of the endogenous flora of mucous membranes. *A. israelii* is always found in the oral cavity when the appropriate anaerobic culture technique is used. It also has been found in the gastrointestinal tract, bronchi, and female genital tract.⁵³

A. actinomycetemcomitans is a fastidious, non-spore-forming, nonmotile, facultatively anaerobic gram-negative coccobacillus that frequently complicates actinomycosis caused by *A. israelii*.^{20,21,37,44,56,59} Further information about this organism is detailed in Chapter 127.

PATHOGENESIS

The organisms that cause actinomycosis normally are found in the oral flora from infancy to adulthood. Actinomycetes are primary colonizers that can initiate the formation of plaque and set the stage for the development of infectious disease, as well as predispose to the formation of caries.^{4,9,12} These bacteria adhere tenaciously to both the hard and soft tissue surfaces of the oral cavity.⁶⁹ Disruption of this mucous membrane probably is the initiating event for oral and cervicofacial disease.¹ The organisms then invade locally and spread without regard to fascial planes. The exact mechanism of this spread is unknown but may be related to the ability of these organisms to suppress part of the host immune system. Organisms of the *Actinomyces* genus have been shown to be chemotactic, to activate lymphocyte blastogenesis, and to stimulate the release of lysosomal enzymes from polymorphonuclear leukocytes and macrophages.^{18,45} In addition, the co-pathogens involved in this infection may reduce local oxygen tension. Dental extractions are associated with mucosal breaks and tissue necrosis and may predispose to oral or cervicofacial actinomycosis.⁴⁷ Hematogenous dissemination can occur eventually but is an uncommon development. Gastrointestinal disease is likely associated with disruption of the mucosal barrier, similar to oral and cervicofacial disease.⁵³ Organisms causing pulmonary actinomycosis most likely reach the lungs through aspiration. Thoracic actinomycosis usually is a complication of localized pulmonary parenchymal infection. Actinomycetes produce enzymes and thus are able to spread by extension into the lungs, pleura, and chest wall without regard to tissue planes.⁶¹ Numerous reports in the literature associate actinomycosis with intrauterine devices (IUDs), and some question exists regarding the association of foreign bodies with actinomycosis.^{5,14}

PATHOLOGY

Actinomycosis is most commonly manifested as a chronic infection with single or multiple indurated swellings. These lesions eventually soften, become fluctuant, and suppurate. The walls are fibrous and firm and often described as wooden, which frequently results in their confusion with neoplasms. Over the course of time, sinus tracts form and extend through the overlying skin or to adjacent bones or tissues. The overlying skin may have a bluish hue.⁵³

Histologically, a typical lesion has a central purulent area containing neutrophils and sulfur granules, surrounded by an outer zone of granulation with collagen fibers and fibroblasts. The sulfur granules are firm, yellowish granules containing the organisms and are virtually diagnostic of actinomycosis, although they can be seen in nocardiosis and botryomycosis. In addition to neutrophils, lymphocytes and plasma cells frequently are seen in the lesions; eosinophils and multinucleated giant cells occasionally are seen.⁵³

CLINICAL MANIFESTATIONS

Actinomycotic infection occurs in three important sites. The order of frequency of occurrence is oral/cervicofacial, abdominal/pelvic, and pulmonary. Actinomycosis resembles several other chronic inflammatory diseases and must be differentiated from mycotic infections, tuberculosis, appendicitis, *Yersinia enterocolitica* pseudoappendicitis, osteomyelitis, amebiasis, hepatic abscess, and other chronic bacterial infections, including nocardiosis.

Because oral and cervicofacial actinomycosis occurs after disruption of the mucous membranes in the mouth or oropharynx, patients who have this type of actinomycosis may have a history of oral surgery, dental procedures, or trauma to the mouth. Clinical findings may include pain, trismus, firm swelling, and fistulae with drainage that contains the characteristic sulfur granules (Figs. 149.1 and 149.2). Patients most commonly have a chronic disease course but may be seen acutely with cellulitis. Infection may spread through the sinus tracts to the cranial bones, which gives rise to meningitis. Bone is not involved early in the disease, but periostitis may develop later. The marked ability of the organisms in this disease to burrow through tissue planes and even bone differentiates actinomycosis from nocardiosis and is an important characteristic of this infection. The cervicofacial type of actinomycosis, or “lumpy jaw,” has the best prognosis. With surgical debridement and excision as an adjunct to proper antibiotic therapy, the disease usually is cured. At least two cases of thyroiditis secondary to actinomycosis have been reported in pediatric patients.^{24,68}

FIG. 149.1 Cervicofacial disease with draining sinus tracts caused by *Actinomyces israelii*.

FIG. 149.2 Abscess containing an actinomycotic granule surrounded by purulent exudate. The peripheral clubbing (arrow) is stained by eosin (hematoxylin and eosin, x52).

Abdominal actinomycosis is the result of disruption of the mucosa of the gastrointestinal tract, and thus, patients may have a history of gastrointestinal surgery, diverticulitis, or appendicitis. The patient also may have a history of trauma to the abdomen. Patients may have chills, fever, night sweats, and weight loss. The course is indolent and similar to that of tuberculous peritonitis. Because appendicitis is the most common predisposing event, on physical examination patients may have a hard, irregular mass in the ileocecal area that softens and then drains to the outside. Extension from such foci usually is by direct continuity (or, rarely, hematogenously) and involves any tissue or organ, including muscle, liver, spleen, kidney, fallopian tubes, ovaries, uterus, testes, bladder, esophagus, or rectum.^{2,3,10,28,33,50} A delayed diagnosis of actinomycosis involving the abdomen or pelvis is typical and is frequently confused with malignancy.²⁹

Hepatic involvement occurs in approximately 15% of cases of abdominal actinomycosis. Involvement of the liver can occur through direct extension from a subdiaphragmatic or subhepatic abscess. It also is a common finding in disseminated actinomycosis.⁵³ Occult disruption of the gastrointestinal mucosa with spread of organisms through the portal vein may provide a portal of entry for the organisms in cases of primary or isolated hepatic disease. Initial symptoms may include fever, abdominal pain, anorexia, weight loss, nausea, vomiting, shoulder pain, back pain, or diarrhea. The course is usually indolent, with 1 to 6 months of symptoms. On physical examination, the patient commonly has fever, abdominal tenderness, and hepatomegaly. A palpable abdominal mass, jaundice, or draining sinuses may be present. Disseminated intravascular coagulation has been reported.⁶⁵ Hepatic actinomycosis has been found in children who have undergone appendectomies.³⁸ Thrombotic thrombocytopenic purpura has been described in association with hepatic actinomycosis in an adult.⁵⁰ Other causes of liver masses included in the differential diagnosis are pyogenic abscess, amebiasis, and malignancy.

Women with IUDs are at risk for the development of pelvic actinomycosis. These patients may have vaginal discharge, pelvic pain, abdominal pain, menorrhagia, fever, a pelvic mass, a history of pelvic inflammatory disease, or a history of prolonged IUD use (Fig. 149.3). The risk is more significant if the IUD has been in place for longer than 2 to 3 years. These devices are thought to cause an inflammatory response in the endometrium with focal necrosis. This anaerobic environment encourages the growth of *A. israelii*. In such patients, removal of the IUD plus treatment with antibiotics is necessary.¹⁴ Pelvic actinomycosis can develop in both men and women; it can appear as a tumorlike mass and be confused with malignancy. A urachus or urachal remnant is also a risk factor.³⁶

Establishing the diagnosis of pulmonary actinomycosis depends on having a high index of suspicion because neither the clinical nor the radiographic findings are specific. Patients may have a history of or risk factors for aspiration. Adults with thoracic actinomycosis usually

have abnormal local defenses, such as chronic bronchitis, bronchiectasis, or emphysema; however, pediatric patients have been shown to have predisposing factors less often.^{30,61} This type of actinomycosis also occurs after the introduction of a colonized foreign body. Patients with oral, cervicofacial, or abdominal actinomycotic infections are at risk for the development of pulmonary infection from direct or hematogenous spread. A history of these preexisting infections should heighten the index of suspicion. Pulmonary actinomycosis may be manifested as an endobronchial infection, a tumorlike lesion, diffuse pneumonia, or a pleural effusion.^{8,11,46} The presence of chronic pleural effusion, underlying lung changes, and periosteal rib involvement is indicative of actinomycosis but seldom is reported.⁶⁷ The principal symptoms include chest pain, fever, productive cough, and weight loss. Hemoptysis has been reported.⁴⁸ The infection frequently dissects along tissue planes and may extend through the chest wall or diaphragm and produce multiple sinuses (Figs. 149.4 and 149.5). These characteristic sinus tracts contain small abscesses and purulent drainage. Empyema necessitans has been reported in one child.⁶² The differential diagnosis of pulmonary actinomycosis includes tuberculosis, lung abscess, nocardiosis, fungal infection, and botryomycosis.

Laryngeal actinomycosis rarely has been reported in older teenagers.⁴¹ Colonization of the oropharynx with these organisms may be involved in the development of obstructive tonsillar hypertrophy.⁴⁷ Several adult cases of pericardial actinomycosis are reported in the literature.¹⁵ Bacteremia is reported in all age groups, including neonates.^{7,15,25,34} Septic arthritis has been reported.³¹ Brain abscess has occurred in a child with complex congenital heart disease (Fig. 149.6).⁴² A case has been reported of purulent meningitis caused by *Actinomyces* species.²³ Actinomycetes

FIG. 149.4 Chest radiograph of a 10-year-old child with chronic pneumonia whose lung biopsy revealed sulfur granules and bacteria in the actinomycoses species.

FIG. 149.5 Computed tomographic image of the same child in Fig. 149.4 revealing bony erosion (arrow) of the ribs next to the infiltrate.

FIG. 149.6 Brain abscess that grew *Actinomyces turicensis*.

have been isolated from nearly every organ in the body, including the kidneys, brain, heart, breasts, mastoids, male genitourinary tract, and eyes.¹² Osteomyelitis is reported in children, often involving the mandible, but other bones have been infected as well.⁵¹ It has been associated with brain abscesses in patients with hereditary hemorrhagic telangiectasia.²⁷ Ocular canaliculitis in pediatric patients has been recently reported.⁷⁰ *Trueperella pyogenes* has been implicated only rarely as a cause of human infection, but cases of septicemia, endocarditis, meningitis, arthritis, empyema, pneumonia, otitis media, cystitis, mastoiditis, appendicitis, and cutaneous infection have been reported.^{13,17}

Actinomycosis does not seem to be associated commonly with human immunodeficiency virus infection. Thoracic, esophageal, oral, and anal cases have been reported, however, and all immunocompromised hosts should be monitored closely for this potential group of pathogens.^{2,3,43,64} Actinomycosis has been reported in patients with chronic granulomatous disease, including cervicofacial, pulmonary, and hepatic infection.⁴⁹ Primary cutaneous actinomycosis caused by *Actinomyces bovis* has been reported in a patient with common variable immunodeficiency.³⁵

A. actinomycetemcomitans is a pathogen in at least 30% of actinomycotic infections³⁷ (see Chapter 127). Failure to recognize this organism and treat it adequately has resulted in clinical relapse and deterioration in patients infected with actinomycosis.^{40,69}

DIAGNOSIS

To establish a definitive diagnosis of actinomycosis, the clinician must isolate the causative organism from tissue or pus from a normally sterile body site, such as the lungs. Isolation of the organism from the oral cavity or the female genital tract without clinical evidence of disease, therefore, is not diagnostic. Because the organisms that cause actinomycosis are exquisitely sensitive to antibiotics, clinical specimens must be obtained before initiating their use. The specimens should be processed carefully to maintain anaerobic conditions. They should undergo routine Gram stain, which will reveal pleomorphic gram-positive rods with or without branching.¹⁸ Gram stain is more sensitive than culture, particularly if the patient has been given antibiotics. Immunofluorescence is available for confirmation of organisms in biopsy specimens with suggestive Gram stains. Growth on media usually appears within 5 to 7 days but may take 2 to 4 weeks.⁵³ Identification methods include RapID ANA II kits (Remel), matrix-associated laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry, and 16S rDNA sequencing.^{16,32,57}

True microbiologic identification of these organisms occurs uncommonly, and the diagnosis most often rests on the clinical picture, along with identification of the characteristic sulfur granules. The sulfur granules may be found by drawing pus from a lesion, on the bandage covering the lesion, or in surgical specimens (see Fig. 149.2). Pus that is poured down the side of a glass will leave sulfur granules adhering to the sides so that the granules can be identified more easily. On hematoxylin and eosin stain, the granules are eosinophilic or variably surrounded by a radiating fringe of eosinophilic clubs. The formation of granules is a hallmark of actinomycosis and is related to a bacterial secretion that cements elements of *Actinomyces* spp. together. However, the formation of granules related to various nonfilamentous bacteria such as *Staphylococcus aureus* or *Pseudomonas* spp. is termed botryomycosis or bacterial pseudomycosis, and they can look grossly similar to the typical sulfur granules of actinomycosis.¹¹ Washed, crushed actinomycotic granules or well-mixed pus in the absence of granules is cultured on a rich medium, such as brain-heart infusion blood agar, blood or chocolate agar if aerotolerant, or anaerobic blood agar if anaerobic. The plates are then incubated anaerobically and aerobically with added carbon dioxide. Plates can be examined after 24 hours and should be held 5 to 7 days for recovery of *Actinomyces* spp.¹⁸

Various imaging modalities have been useful in diagnosing and characterizing actinomycosis. Computed tomography has been shown to help differentiate between inflammatory masses and tumors. In addition, the location, extension, and relationship between the mass and surrounding structures can be defined better. Ultrasonography has been shown in one report to reveal a mass with an ill-defined margin that was hypoechoic with intrinsic hyperechoic spots.⁵⁵ Magnetic resonance imaging has been used for diagnosing actinomycotic brain abscess, as well as actinomycosis of the chest, spine, soft tissues, and mandible.^{30,42,51}

Because of the frequency of coinfection with this organism in cases of actinomycosis, attempts always should be made to isolate *A. actinomycetemcomitans* in these patients. Further details are found in Chapter 127.

TREATMENT

The mainstays of therapy for actinomycosis remain surgical debridement or removal of the lesion and prolonged antimicrobial therapy. Most experts still recommend drainage of abscesses, fistulotomy, sinus tract excision, and debulking of large masses, although numerous successful outcomes with antimicrobial therapy alone are reported in the literature.^{38,52,53} The option to treat medically and observe for clinical response seems reasonable in a stable, noncritical patient.

The traditionally recommended total duration of therapy ranges from 6 to 12 months. There are, however, numerous reports in the literature of successful treatment with various combinations of intravenous followed by oral therapy for much shorter periods of time. Thoracic actinomycosis has been treated successfully with a total duration of therapy of only 4 months.⁵⁸ Two studies in adults with thoracic actinomycosis revealed good success rates with less than 14 days of intravenous therapy followed by prolonged oral treatments. Some of those patients required surgery.^{6,63} Another study in adults with cervicofacial disease reported good success rates with surgical debridement and intravenous penicillin and metronidazole followed by oral therapy for a total duration of 2 to 4 weeks.³⁹ Because the disease is an uncommon occurrence in children and no significant randomized prospective treatment trials have been performed, most authors still recommend a few weeks of intravenous therapy followed by prolonged oral therapy. The total duration of therapy is based on clinical and radiographic follow-up. Certainly in cases for which surgical debridement or incision and drainage have been performed, a shorter duration of therapy would be reasonable provided that close clinical follow-up can be ensured. Osteomyelitis may require longer therapy.⁵¹ Failure to respond to adequate treatment has been noted in patients with underlying malignancy.

The antibiotic of choice for treatment of actinomycosis is penicillin. For patients who are allergic to penicillin, tetracycline or erythromycin is acceptable. Other alternatives are clindamycin and the third-generation cephalosporins.⁵⁸ Susceptibility breakpoints have been established for

linezolid and meropenem for aerotolerant *Actinomyces*. Most isolates are clearly resistant to ciprofloxacin and metronidazole.^{19,60} Administration of daily ceftriaxone for 3 weeks followed by prolonged administration of ampicillin was effective treatment in one case.⁶¹

A. actinomycetemcomitans is susceptible to the third-generation cephalosporins, rifampin, trimethoprim-sulfamethoxazole, aminoglycosides, quinolones, tetracycline, azithromycin, and chloramphenicol. It also is susceptible to penicillin and ampicillin in vitro, but test results do not necessarily correlate with clinical outcome. Vancomycin, erythromycin, and clindamycin have no significant activity against this organism.

Bacteroides*, *Fusobacterium*, *Prevotella*, and *Porphyromonas

Catherine Foster • Lucila Marquez • Steven C. Buckingham

The most clinically important anaerobic gram-negative bacilli include *Bacteroides*, *Fusobacterium*, and *Prevotella*, along with *Porphyromonas*. These bacteria, like other anaerobes, normally colonize the skin and mucosal surfaces of humans. Anaerobic gram-negative rods can cause infections of various body sites in children, although their importance as pediatric pathogens has historically been underappreciated. Many infections with these and other anaerobic pathogens are never diagnosed as such because clinicians fail to use appropriate methods for collection or transportation of specimens or because laboratories fail to use appropriate methods for the isolation and identification of anaerobic bacteria.

BACTERIOLOGY AND TAXONOMY

Bacteria belonging to the genera *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Porphyromonas* are obligately anaerobic gram-negative bacilli. The taxonomic classification of these and other anaerobic bacteria has undergone considerable revision in recent decades, based largely on the characterization of the bacteria with the use of nucleic acid analyses.

***Bacteroides* Species**

Bacteroides spp. are strictly anaerobic, nonmotile gram-negative rods, about 0.5 to 2.0×1.6 to 12 μm , with rounded ends. In general, these bacteria are nonpigmented, saccharolytic, and bile resistant, and on blood agar they form smooth, white to gray colonies that are 1 to 3 mm in diameter. In the 1980s, the genus *Bacteroides* comprised a large and heterogeneous group of anaerobic gram-negative bacilli, but over the past 3 decades, many species formerly assigned to this genus have been reassigned to other genera.¹¹⁹ The most notable taxonomic shift occurred between 1988 and 1990, when numerous *Bacteroides* spp. were reclassified into the newly created genera *Prevotella* and *Porphyromonas*.^{116,117,118} Historically, the *Bacteroides* spp. most frequently recovered in clinical specimens have been collectively classified as the so-called *Bacteroides fragilis* group, consisting of *Bacteroides fragilis*, *Bacteroides distasonis*,

Bacteroides ovatus, *Bacteroides thetaiotaomicron*, *Bacteroides vulgatus*, and others. Taxonomic revisions based on nucleic acid analyses have disrupted even this close-knit group, because *B. distasonis*, *B. goldsteinii*, and *B. merdae* have been reclassified under the genus *Parabacteroides* and *Bacteroides forsythus* has been renamed *Tannerella forsythensis*.^{112,113}

Today, most previously recognized *Bacteroides* spp. that were not members of the *B. fragilis* group have been moved to other genera. In 2010, *Bacteroides ureolyticus* was reclassified as *Campylobacter ureolyticus*.¹³⁴

Resistance to multiple classes of antibiotics is a hallmark of *Bacteroides* spp., and resistance even to drugs traditionally considered to have broad activity against anaerobes has increased substantially over the past 2 decades. Most *Bacteroides* spp., and virtually all members of the *B. fragilis* group, produce a class 2e cephalosporinase, encoded by the *cepA* gene, which confers broad resistance to penicillins and first- and third-generation cephalosporins. This β -lactamase, however, is uniformly neutralized by the β -lactamase inhibitors clavulanate, sulbactam, and tazobactam. Another, less frequently encountered β -lactamase, encoded by *cfxA*, confers resistance to cefoxitin. Resistance to β -lactams also can result, less commonly, from alterations in the penicillin-binding proteins, PB1 and PB2, or from porin mutations, which alter the permeability of the bacterial outer membrane to β -lactams.^{62,74,95,119}

Resistance to carbapenems remains rare among *Bacteroides* spp., although recent reports from Turkey and Taiwan reported resistance rates of 6% to imipenem and 8% to meropenem among *B. fragilis* group isolates.^{91,95,132} Carbapenem resistance results from production of a class B metallo- β -lactamase encoded by either *cfiA* or *ccrA*. Expression of these genes requires the presence of special insertion sequences upstream of the gene, which act as promoters. The resulting β -lactamase renders the organism resistant not only to carbapenems but also to all β -lactams, including the penicillin/ β -lactamase inhibitor combinations (i.e., amoxicillin-clavulanate, ampicillin-sulbactam, and piperacillin-tazobactam).^{74,95,133}

Resistance to clindamycin, which has been increasingly documented among *Bacteroides* isolates in recent decades, usually results from MLS-type ribosomal alterations coded by various *erm* genes, although other

mechanisms apparently account for resistance in some isolates.^{74,95} Metronidazole resistance, which remains rare, results from the production of nitroimidazole reductases encoded by any of seven known *nim* genes. Expression of these genes requires the presence of upstream insertion sequences, which act as promoters. In some cases, metronidazole resistance has been documented in *Bacteroides* isolates lacking *nim* genes, following prolonged exposure to the drug.^{62,74,95} Resistance to moxifloxacin, which has increased rapidly since the late 1990s, results either from alterations in the DNA gyrase genes *gyrA* and *gyrB* or from increased production of efflux pumps.^{74,95} Most *B. fragilis* group isolates are resistant to tetracycline, owing to ribosomal alterations encoded by *tetQ*, *tetM*, or *tet36* genes. Tigecycline has much better activity against *Bacteroides* spp., although some isolates are resistant by virtue of their production of a tetracycline-degrading mono-oxygenase encoded by *tetX*.⁹⁵

Prevotella Species and Porphyromonas Species

The genus *Prevotella* includes more than 40 recognized species, all of which are moderately saccharolytic, bile-sensitive gram-negative bacilli that were formerly classified under the genus *Bacteroides*. Some species are pigmented (e.g., *Prevotella corporis*, *Prevotella denticola*, *Prevotella intermedia*, *Prevotella loescheii*, *Prevotella melaninogenica*, and *Prevotella nigrescens*), whereas others are nonpigmented (e.g., *Prevotella bivia*, *Prevotella disiens*, *Prevotella oris*, *Prevotella buccae*, and *Prevotella heparinolytica*).^{80,119}

Compared with the *B. fragilis* group, *Prevotella* spp. are generally more susceptible to antibiotics. Resistance to penicillin is frequently observed, owing to the production of β -lactamases coded by *cfxA* or other genes, although most isolates remain susceptible to third-generation cephalosporins, cefoxitin, carbapenems, and penicillin/ β -lactamase inhibitor combinations.^{74,95} Resistance to metronidazole, which is mediated by *nim*-encoded production of nitroimidazole reductases, occurs infrequently. Clindamycin resistance, which has increased in prevalence in recent years, is associated with *ermF*- or *ermG*-mediated ribosomal modification.⁹⁵ Data on moxifloxacin's activity against *Prevotella* spp. are sparse, but available studies indicate that most isolates are susceptible.^{68,72,89,91,141} *Prevotella* spp. are frequently resistant to tetracycline, owing to ribosomal alterations encoded by the *tetQ*, *tetM*, or *tetW* genes. Available data suggest that tigecycline, however, is highly active against *Prevotella* strains.⁹⁵

The genus *Porphyromonas* consists of pigmented or nonpigmented gram-negative bacilli that, like *Prevotella* spp., were formerly classified under the genus *Bacteroides*. Unlike *Prevotella* spp., *Porphyromonas* spp. are asaccharolytic or only weakly saccharolytic.^{80,119} In contrast to *Bacteroides* and *Prevotella* spp., antibiotic resistance is unusual among *Porphyromonas* spp. Penicillin resistance, mediated by *cfxA*-encoded β -lactamase production, occurs in a minority of clinical specimens but is somewhat more frequent in animal-derived specimens.^{74,95,119} Carbapenems and penicillin/ β -lactamase inhibitor combinations are uniformly active against *Porphyromonas* spp. Resistance to clindamycin, associated with *ermF* and *ermG* genes, occurs in fewer than 10% of strains. Resistance to metronidazole and tetracycline, although described, is only rarely observed.⁹⁵

Fusobacterium Species

Fusobacterium spp. are nonmotile, thin, long, filamentous anaerobic gram-negative rods that metabolize peptones or carbohydrates to produce butyric acid. Since the early 1980s, several new *Fusobacterium* spp. have been described (*Fusobacterium periodonticum*, *Fusobacterium simiae*, *Fusobacterium ulcerans*, *Fusobacterium equinum*, and *Fusobacterium canifelinum*), whereas two long-standing members of the genus have been reclassified to other genera (*Fusobacterium plautii* and *Fusobacterium prausnitzii*). Moreover, three newly described species were subsequently reclassified to other genera (*Fusobacterium alocis*, *Fusobacterium sulci*, and *Fusobacterium polysaccharolyticum*), and another (*Fusobacterium pseudonecrophorum*) was described but found to be identical to *Fusobacterium varium*.¹¹⁹ The type species, *Fusobacterium nucleatum*, is the one most frequently recovered from clinical specimens.¹²

Fusobacterium spp. are usually susceptible to penicillin, third-generation cephalosporins, clindamycin, and moxifloxacin, and more than 90% of strains are susceptible to cefoxitin, penicillin/ β -lactamase

inhibitor combinations, carbapenems, and metronidazole. In one study, all isolates of *F. nucleatum* and *Fusobacterium necrophorum* were susceptible to imipenem, amoxicillin-clavulanate, cefoxitin, and clindamycin. Isolates of the *Fusobacterium mortiferum/varium* group, however, demonstrated reduced susceptibility rates to imipenem (85%), amoxicillin-clavulanate (90%), and clindamycin (55%).¹³⁸ Tetracycline resistance, associated with *tetW* and *tetM* genes, is unusual among *Fusobacterium* spp. but has been described.^{74,95} Erythromycin has unreliable activity against *Fusobacterium* spp., but limited data suggest that azithromycin is active against more than 90% of isolates in vitro.^{67,71,80,88,136}

EPIDEMIOLOGY

A variety of aerobic and anaerobic bacteria normally colonize the skin and mucosal surfaces of healthy human hosts and are collectively referred to as the human microbiome. The human microbiome is an area of active scientific investigation. Through the use of advanced bacterial sequencing technologies, significant progress has been made in identifying the numerous microorganisms that comprise the microbiome, although a full understanding of the factors that influence colonization and the complex interactions between microbiota and hosts regarding health and disease has not been reached. In the oral cavity, gastrointestinal tract, and female genital tract, anaerobes vastly outnumber aerobes; in the colon, where hundreds of different anaerobic species are found, anaerobes account for more than 99.9% of all bacteria present.^{42,95}

The predominance of anaerobes among the normal microbial flora stands in stark contrast to the infrequency with which these organisms are identified in clinical specimens. Nonetheless, several types of infections routinely involve anaerobic bacteria, such as sinogenic infections, odontogenic infections, human and animal bite-associated infections, aspiration pneumonia, peritonitis in the presence of a ruptured viscus, amnionitis, endometritis, necrotizing infections of soft tissues, and abscesses of the brain, lung, tubo-ovarian tract, and perirectal area. Underlying conditions that predispose patients to anaerobic infections include trauma, foreign bodies, malignancy, recent surgery, shock, colitis, vascular disease, and current or recent infection with aerobic or facultative organisms.⁵⁰ In general, anaerobic infections occur less frequently in children than in adults, probably because children are less likely than are adults to have these types of predisposing conditions.

Taxonomic revisions aside, organisms traditionally classified as belonging to the *B. fragilis* group comprise much of the normal human colonic flora and also form part of the normal flora of the female genital tract. *Bacteroides* spp., which are the most frequently recovered anaerobic bacteria from clinical specimens, are frequently found in intraabdominal infections, especially abscesses, and occasionally in extraabdominal infections, such as aspiration pneumonia, chronic otitis media, and brain abscesses.^{67,80}

Prevotella spp. and *Porphyromonas* spp. are normal inhabitants of the oral cavity, gastrointestinal tract, and female urogenital tract of humans. These organisms are associated with infections in a diverse range of body sites, most commonly including abscesses of the head and neck region, chronic otitis media, sinusitis, aspiration pneumonia, and intraabdominal infections. In a series of 504 pediatric clinical isolates of *Prevotella* and *Porphyromonas* spp., the most frequently recovered organisms were *Prevotella melaninogenica* (32%), *Prevotella intermedia* (21%), *Porphyromonas asaccharolytica* (17%), *Prevotella oris-buccae* (11%), and *Prevotella oralis* (11%).³³ *Prevotella bivia* and *Prevotella disiens* have been associated with genital tract infections in female adults, although they may also be recovered from oral infections. *Prevotella intermedia*, *Porphyromonas gingivalis*, and *Porphyromonas endodontalis* are particularly involved in adult periodontal disease and various dental infections.^{67,80}

Fusobacterium spp. also constitute part of the normal flora of the human oral cavity and gastrointestinal tract, and they are associated with a range of pediatric infections similar to those involving *Prevotella* spp. and *Porphyromonas* spp. The *Fusobacterium* spp. most commonly isolated from clinical specimens is *F. nucleatum*, followed by *F. necrophorum*; organisms of the *F. varium-mortiferum* group are rarely recovered from clinical specimens. The virulent pathogen *F. necrophorum* is occasionally isolated from peritonsillar abscesses and is the principal cause of Lemierre disease (see later discussion).^{28,67,80,95,44}

PATHOGENESIS

For the most part, anaerobic bacteria and humans enjoy a mutually beneficial relationship. The colon, for example, provides a home for the billions of anaerobic bacteria that make up the normal intestinal flora of humans. In turn, the presence of *Bacteroides* spp. and other colonizing anaerobic flora serve beneficial functions for humans, through such mechanisms as occupying an ecologic niche that might otherwise be invaded by enteric pathogens (a process known as colonization resistance); inducing tolerance to microbial epitopes, thereby serving to regulate the immune system; and breaking down otherwise indigestible plant polysaccharides while also producing vitamin K. Infections with anaerobic bacteria usually arise either because mucosal surfaces become disrupted, allowing these opportunistic pathogens access to normally sterile tissues, or because anaerobes are directly inoculated into such tissues, as occurs with traumatic or bite wounds.^{95,142} Pathologic characteristics of anaerobic infections include suppuration, abscess formation, tissue destruction, foul odor, and, occasionally, formation of gas.

The pathogenesis of anaerobic infections reflects a complex interaction among bacterial virulence factors, host defense mechanisms, and synergy with other organisms. The elucidation of the complete genome sequence of *B. fragilis*, *B. thetaiotaomicron*, *F. nucleatum*, and *Porphyromonas gingivalis* has facilitated the identification of a host of genes encoding putative virulence determinants. These include gene sequences encoding fimbriae, hemagglutinins, proteinases (e.g., immunoglobulin proteases and collagenases), and hemolysins, which collectively serve to enhance pathogenicity by facilitating adherence to other bacteria and to host cells, thus disrupting the integrity of host tissues and interfering with host immune responses.^{56,75,81,87,98,101,142}

Another key virulence factor for these bacteria is their possession of a capsule, which allows the organisms to evade phagocytosis and which is important to abscess formation.^{24,33,98,101} The genomes of *B. fragilis* and *Porphyromonas gingivalis* also include aerotolerance operons, which encode proteins that allow the organisms to survive despite exposure to limited quantities of oxygen.^{98,129} Moreover, enterotoxin-producing *B. fragilis* isolates have been identified in livestock and humans, and the presence of these bacteria has been associated with cases of diarrhea in children and adults.^{75,95,139}

Anaerobic infections are typically polymicrobial and often involve multiple species of both aerobic and anaerobic flora. Experiments in mice, which evaluated mixed aerobic-anaerobic infections involving *Bacteroides* spp., *Prevotella* spp., and *Porphyromonas* spp., demonstrated that while the growth of both aerobes and anaerobes is enhanced in such infections, the enhancement of the aerobes' growth is by far more pronounced. The factors responsible for aerobic-anaerobic synergism are not fully understood. Some have postulated that the bacterial species involved assist one another by providing essential growth factors, interfering with phagocytic uptake and killing, secreting β -lactamase into the extracellular milieu, or altering the oxidation-reduction potential of infected tissue.^{22,33}

CLINICAL MANIFESTATIONS

Serious anaerobic infections are seen more frequently in compromised hosts or in neonates than in otherwise healthy children. Outcomes of severe anaerobic infections are tied to patients' underlying disease states and to the promptness with which appropriate antimicrobial therapy is started.

Bacteremia and Endocarditis

Anaerobic bacteremia is unusual in children; when it does occur, it usually arises from a primary focal anaerobic or mixed aerobic-anaerobic infection. The risk for anaerobic bacteremia is elevated in patients compromised by a variety of conditions, including recent gastrointestinal or gynecologic surgery, dental manipulation, malignancy, immunosuppression, neonatal status, diabetes mellitus, and asplenia.^{18,36,42,95} Among neonates, risk factors for anaerobic bacteremia include premature birth, maternal perinatal complications (e.g., premature rupture of membranes), and necrotizing enterocolitis.²⁷

Overall, *B. fragilis* is the most frequently identified anaerobic bloodstream isolate. The specific anaerobes recovered from blood cultures vary depending on the entry portal: when the primary focus is in the gastrointestinal tract, *Bacteroides* spp. and *Clostridium* spp. predominate; in cases associated with oropharyngeal or pulmonary foci, pigmented *Prevotella* and *Porphyromonas* spp., *Fusobacterium* spp., and anaerobic gram-positive cocci are more likely. The presenting features of anaerobic bacteremia in children are similar to those associated with bacteremia caused by aerobic organisms. Fever, chills, and leukocytosis are frequently encountered, whereas hypotension, shock, and disseminated intravascular coagulation are less common findings. Mortality rates of 5% to 10% have been reported among children with anaerobic bacteremia.^{18,36,42,95} Among neonates, reported mortality is higher among those with bacteremia caused by *Bacteroides* spp. (34%) than with other anaerobic species (17%).²⁷

Although exceedingly uncommon among the pediatric population, there are case reports of anaerobic endocarditis. The most common source for *B. fragilis* group endocarditis is the gastrointestinal system, whereas the head and neck are the most common origin for *Fusobacterium* and *Bacteroides* species endocarditis. Anaerobic endocarditis due to *F. necrophorum* has been observed as a rare complication of Lemierre syndrome and has a strong association with thromboembolic events. The mortality rate for patients with anaerobic infective endocarditis is high and ranges from 21% to 43%.^{41,110,115}

Head and Neck Infections

Odontogenic Infections

Anaerobes are usually involved in infections of dental origin, such as gingivitis, periodontitis, and periapical and dental abscesses. The most commonly implicated anaerobes in such infections are *Prevotella* spp. (particularly *P. melaninogenica*) and *Porphyromonas* spp. (particularly *P. gingivalis*).^{42,95} Often these are found in mixed infections along with oral aerobic flora, including *Streptococcus salivarius* and microaerophilic streptococci. *Fusobacterium* spp. can also be recovered in odontogenic infections and are particularly associated with the ulcerative form of gingivitis known as Vincent angina (trench mouth).⁴²

Perioral Infections

Prevotella and *Porphyromonas* spp. are also frequently recovered from various suppurative perioral infections, such as retropharyngeal and peritonsillar abscesses, cervical lymphadenitis, deep neck abscesses, thyroiditis, parotitis, infected cysts, and postsurgical wound infections involving the oral cavity. Occasionally, these infections also involve *Fusobacterium* spp., *Bacteroides* spp., and/or anaerobic gram-positive cocci, along with oral and nasopharyngeal aerobic flora.

Tonsillitis

Anaerobes likely play a role in the pathogenesis of acute tonsillitis.⁴⁵ A prospective study compared bacterial culture results from patients with peritonsillar abscesses undergoing acute tonsillectomy to patients undergoing elective tonsillectomy and found that *Fusobacterium necrophorum* and *Streptococcus* group A (GAS) were isolated significantly more frequently from the tonsillar cores of patients with peritonsillar abscesses than from the tonsillar cores of patients who underwent elective tonsillectomy. Additionally, the peritonsillar abscess patients had the same incidence of *F. necrophorum* from the abscessed tonsil as from the contralateral, nonabscessed tonsil, suggesting that the growth of *F. necrophorum* is not a result of an overgrowth phenomenon once the abscess is formed, but that *F. necrophorum* is a pathogen in both peritonsillar abscesses and acute tonsillitis.⁸³ Anaerobes, including *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp., are also thought to be involved in the pathogenesis of recurrent or chronic tonsillitis, and production of β -lactamase by these organisms has been postulated to explain the failure of penicillin to eradicate pharyngeal carriage of *Streptococcus pyogenes* in some children.⁴²

Lemierre Disease

Rarely, pharyngotonsillitis and tonsillar abscesses can be complicated by Lemierre disease (also known as postanginal sepsis or human necrobacillosis), a syndrome characterized by bacteremia, septic

thrombophlebitis of the internal jugular and facial veins, and metastatic emboli to the lung and other distant organs. *F. necrophorum* is responsible for more than 80% of all cases. Occasionally, *F. nucleatum* or other *Fusobacterium* spp. are involved, often in combination with other anaerobic or aerobic flora. Lemierre disease is most common among adolescents and young adults but can occur in patients of any age. In the preantibiotic era, most patients with this syndrome died of overwhelming sepsis; more recently, mortality rates of 4% to 22% have been reported.^{95,108,140}

Deep Neck Infections

Deep neck infections are usually polymicrobial and tend to follow oral, dental, and pharyngeal infections. The predominant organisms are *S. aureus*, group A β -hemolytic streptococci, and anaerobic bacteria of oral origin, including *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp.⁴³ In an analysis of 634 patients with deep neck infections, 32% had both aerobic and anaerobic bacteria isolated. The most common aerobic bacteria were *Streptococcus pyogenes* and *Staphylococcus aureus*, and the most common anaerobic bacteria were *Peptostreptococcus* followed by *Prevotella*.⁵³

Otitis Media and Mastoiditis

Although anaerobic gram-negative bacilli have not been implicated in the pathogenesis of acute otitis media, these organisms are present in up to 50% of middle ear fluid cultures from patients with chronic suppurative otitis media or infected cholesteatomas and in nearly all patients with chronic mastoiditis. The microbial pathogens recovered from such patients include *Prevotella*, *Porphyromonas*, *Bacteroides*, and *Fusobacterium* spp., along with anaerobic gram-positive cocci and various aerobes, most notably *Staphylococcus aureus* and *Pseudomonas aeruginosa*.^{42,47} *Fusobacterium* spp. have been isolated from children with acute mastoiditis. In an Israeli study, seven children were diagnosed with complicated mastoiditis with abscess formation caused by *F. necrophorum*. Four patients were found to have epidural abscess, three patients had evidence of osteomyelitis beyond the mastoid bone, and four children had imaging evidence of sinus vein thrombosis. All seven children underwent cortical mastoidectomy with tympanostomy tube insertion, and two required multiple surgical interventions.¹⁴⁵

Rhinosinusitis

Anaerobes are not usually associated with acute bacterial rhinosinusitis, but they are frequently implicated as pathogens in children with chronic sinusitis (symptoms for >30 days). In one study, sinus aspirate cultures from 37 children with chronic sinusitis yielded an average of 2.7 anaerobes and 0.6 aerobes per patient. Anaerobic pathogens associated with chronic sinusitis include *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp., along with members of the *B. fragilis* group.^{20,28,42} Additionally, anaerobes are well-recognized pathogens in the setting of complications of sinusitis, including orbital abscesses and intracranial extension.

Central Nervous System

Anaerobes can be isolated from the majority of intracranial abscesses that arise in association with sinusitis, otitis media, or dental infection. In one study, cultures of brain abscess specimens from 23 children yielded 11 aerobic and 44 anaerobic isolates, and cultures of subdural empyema fluid from 16 children yielded six aerobic and 35 anaerobic isolates. Anaerobic gram-positive cocci were the anaerobes most frequently recovered from these patients, followed by *Fusobacterium* spp. (especially *F. nucleatum*), *Bacteroides* spp. (including *B. fragilis* group members), *Prevotella* spp., and *Actinomyces* spp.²⁶ A similar range of anaerobes have been isolated, alone or along with aerobes, from epidural abscesses found in patients (primarily boys aged 10 to 14 years) with frontal sinusitis complicated by a Pott puffy tumor.^{4,5,65} *B. fragilis* group members have been particularly associated with temporal lobe abscesses arising from chronic otitis media.²

Fusobacterial central nervous system infection in children can occur in relation to chronic sinusitis or Lemierre disease. In a pediatric study performed in Israel, 27 children with fusobacterial infections were found to have a high frequency of neurologic manifestations at presentation, including most commonly seizures (30%). Frequent

thrombotic complications were also observed. Fifteen children (56%) underwent brain imaging, and in seven of these children, a thrombus was identified either in a sinus vein or in an internal jugular vein.⁹⁴

Anaerobic meningitis occurs rarely in children. The symptoms, signs, and laboratory characteristics of children with anaerobic meningitis are similar to those of children with meningitis caused by more common bacterial pathogens. Unlike most anaerobic infections, meningitis is often monomicrobial, and mixed infections involving aerobes and anaerobes are unusual. The anaerobes most frequently recovered from cerebrospinal fluid cultures are *B. fragilis*, other *Bacteroides* spp., *F. necrophorum*, other *Fusobacterium* spp., and *Clostridium* spp. Meningitis caused by *Bacteroides* spp. generally occurs as a complication of a preceding anaerobic infection of the oropharynx or lower respiratory tract or of an underlying gastrointestinal insult (e.g., recent surgery or necrotizing enterocolitis). Meningitis caused by *F. necrophorum* in children is frequently associated with an otogenic focus.³⁸

Intraabdominal Infections

Secondary peritonitis occurs when the intestinal wall is disrupted (e.g., by perforation of an inflamed appendix or surgical misadventure) and enteric bacteria consequently gain access to the peritoneal cavity. Over time the peritoneal infection may evolve, resulting in the formation of one or more intraabdominal abscesses.^{42,95} Secondary peritonitis and intraabdominal abscesses are almost always polymicrobial processes involving a mixed flora of anaerobes and aerobes. *B. fragilis* and other members of the *B. fragilis* group are recovered in most cultures of peritoneal or abscess fluid from patients with such infections; *Prevotella* and *Fusobacterium* spp. are also frequently implicated. Other anaerobic bacteria, including *Clostridium* spp., *Lactobacillus* spp., and anaerobic gram-positive cocci, are also commonly involved. The aerobic flora most frequently recovered in these infections include *Escherichia coli*, viridans streptococci, *Klebsiella* spp., *P. aeruginosa*, and *Enterococcus* spp.^{9,19,90,96,123}

Anaerobic gram-negative bacilli are also frequently present, as part of a mixed aerobic-anaerobic flora, in abscesses of the liver, spleen, and retroperitoneal space. The anaerobic bacteria most frequently recovered from liver abscesses are anaerobic gram-positive cocci, followed by *Bacteroides* spp., *Fusobacterium* spp., and *Prevotella* spp.^{33,49,106} Splenic abscesses are associated with a similar range of anaerobic flora.³³ In a study of retroperitoneal abscess cultures in children, the most frequently isolated anaerobes were *Bacteroides* spp., followed by gram-positive cocci and *Prevotella* spp.³⁵

Sexually active adolescent females are at risk for pelvic inflammatory disease and its complications (e.g., tubo-ovarian abscess). In addition to aerobic sexually transmitted organisms (e.g., *Chlamydia trachomatis* and *Neisseria gonorrhoeae*), these infections frequently involve anaerobic gram-negative bacilli, which originate from the normal vaginal flora and include *Prevotella* species (especially *P. bivia*, *P. disiens*, and *P. melaninogenica*), *Porphyromonas* spp., and *B. fragilis* group organisms. Anaerobic gram-positive cocci and *Clostridium* spp. may also be involved.^{42,95}

Skin and Soft Tissue Infections

Cutaneous abscesses in children can be polymicrobial, involving both aerobic and anaerobic bacteria. Aerobes (particularly *S. aureus*) predominate in infections of the hand, neck, leg, and trunk regions, whereas anaerobes are more frequently recovered in infections of the vulvovaginal, buttocks, perirectal, finger, nail bed, and head regions.⁴⁸ A similar regional distribution of aerobes and anaerobes also occurs in cases of cellulitis.³⁰ The anaerobes most likely to be recovered from infections near the perirectal area include, not surprisingly, *B. fragilis* group and *Clostridium* spp.; infections closer to the oropharynx usually involve oral flora, such as *Prevotella* spp., *Porphyromonas* spp., *Fusobacterium* spp., and anaerobic gram-positive cocci. A wide variety of aerobic and anaerobic flora, including anaerobic gram-negative bacilli, can be isolated from sundry skin infections such as paronychia, infected burn wounds, pilonidal cysts, gastrostomy or tracheostomy site infections, and secondary infections of scabies lesions.^{21,29,31,42,46,50} Anaerobes are also a part of the normal soil flora, and thus can be isolated from wounds complicated by heavy dirt or soil contamination. In the pediatric population, such

wounds can include traumatic lawn-mower injuries.^{40,52} Bacteria of the normal oral flora of humans and animals figure prominently in infected bite wounds. Such infections are frequently polymicrobial and usually involve a mix of aerobic and anaerobic bacteria. In infected human bite wounds, the most commonly involved anaerobes are *Fusobacterium* spp. (especially *F. nucleatum*) and *Prevotella* spp. (especially *P. melaninogenica*, *P. buccae*, and *P. intermedia*), whereas the predominant aerobic pathogens are *Streptococcus anginosus*, *Staphylococcus aureus*, and *Eikenella corrodens*.¹²⁷ In infections arising from dog and cat bite wounds, the most frequently isolated anaerobes are *Fusobacterium* spp. (especially *F. nucleatum*), *Bacteroides* spp. (especially *B. pyogenes*, previously designated *B. tectum*), *Porphyromonas* spp., and *Prevotella* spp. (especially *P. heparinolytica*), whereas the most frequently isolated aerobes are *Pasteurella* spp., *Staphylococcus* spp., and *Streptococcus* spp.¹²⁸ Anaerobic gram-negative bacilli are occasionally involved in complicated skin and soft tissue infections. Crepitant cellulitis is a superficial infection that is associated with less systemic toxicity but more noticeable crepitus than clostridial myonecrosis. The usual causative pathogen is *Clostridium perfringens*, but crepitant cellulitis can also result from infection with combinations of aerobic bacteria with *B. fragilis* and/or other anaerobic pathogens. Necrotizing fasciitis is a dreaded soft tissue infection that can be rapidly progressive. In one type of necrotizing fasciitis, anaerobes such as *Bacteroides* spp. and anaerobic gram-positive cocci are frequently recovered, usually in association with various aerobic enteric flora. This type should be distinguished from necrotizing fasciitis caused by *S. pyogenes* (or, less frequently, by groups B, C or G streptococci), in which anaerobes are generally not involved.^{60,95}

Bone and Joint Infections

Septic arthritis caused by anaerobic bacteria is rare in both children and adults and, unlike most anaerobic infections, is usually not polymicrobial. Most cases result from anaerobic bacteremia with gram-negative rods (especially *Fusobacterium* spp. or the *B. fragilis* group) or anaerobic gram-positive cocci. In some cases, the presence of anaerobes is suggested by foul-smelling synovial fluid, gas under pressure within the joint, negative synovial fluid cultures in the clinical picture of septic arthritis, or an anaerobic infection elsewhere in the patient.^{37,95}

Anaerobic osteomyelitis is also quite uncommon in children. When it does occur, it generally results from direct extension from a contiguous focus, rather than via hematogenous seeding. In a series of 26 children with culture-proven anaerobic osteomyelitis, all had preexisting anaerobic infections at adjacent sites or other predisposing conditions for anaerobic infection. Culture results reflected those of the underlying anaerobic infection or of the normal flora of the nearest mucous membrane surface. Anaerobic gram-positive cocci were isolated most frequently, followed by pigmented *Prevotella* and *Porphyromonas* spp., *Fusobacterium* spp., *Clostridium* spp., *Prevotella oralis*, and *Bacteroides* spp. All but two patients had polymicrobial infections; in 10 patients, aerobic flora were also recovered. In contrast to acute hematogenous osteomyelitis, these cases presented insidiously; the mean duration of symptoms before presentation was 21 days.^{23,37}

Pleuropulmonary Infections

Anaerobic infections of the lower respiratory tract are rare in healthy children. They are, however, relatively common in children with tracheoesophageal malformations or central nervous system abnormalities that impair cough reflexes. Such children are predisposed toward aspirating not only food, milk, and vomitus but also their oropharyngeal secretions. Thus, aspiration pneumonia is usually a polymicrobial process involving both aerobic and anaerobic flora of the oral cavity. The risk for pneumonia is further elevated in children with poor oral hygiene, gingivitis, or periodontitis. If untreated, aspiration pneumonia can follow a progressive course with the development of single or multiple lung abscess and/or pleural empyema. The predominant anaerobes recovered from children with aspiration pneumonia (including those with and without associated lung abscesses) are anaerobic gram-positive cocci, followed by *Prevotella* and *Porphyromonas* spp., *F. nucleatum*, *B. fragilis* group members, and other *Bacteroides* spp. The major aerobic copathogens implicated in these infections include *P. aeruginosa*, *Streptococcus pneumoniae*, *E. coli*, *Klebsiella pneumoniae*, and *S. aureus*.^{39,95}

Anaerobes are occasionally isolated from pleural fluid cultures of patients with pleural empyema, and it is possible that they account for at least some cases of empyema in which routine bacterial cultures are negative. In a study of 104 children with pleural empyema, anaerobes were isolated from five adolescents, in all cases along with other aerobic or anaerobic oral flora. Predisposing conditions in these patients were pneumonia in four and alcohol intoxication in one.⁶⁴ In another study of 72 neurologically impaired children with empyema, anaerobic bacteria were recovered in 24% of patients. Anaerobic pleural empyema was associated with the presence of other anaerobic infections in or near the respiratory tract, including aspiration pneumonia, lung abscess, subdiaphragmatic abscess, and dental or oropharyngeal abscess. Anaerobes isolated from these patients included *B. fragilis* group members, pigmented *Prevotella* and *Porphyromonas* spp., *Fusobacterium* spp., and anaerobic gram-positive cocci.^{25,39}

Anaerobes are occasionally isolated from lower respiratory tract specimens of children with ventilator-associated pneumonia.^{32,34} In one study, anaerobes were recovered from nine of 10 sputum culture specimens obtained using protective brush catheters, either alone (three children) or as part of a mixed infection with aerobic bacteria (six children). The anaerobic flora recovered in these children included pigmented *Prevotella* and *Porphyromonas* spp. (five children), anaerobic gram-positive cocci (four children), *Fusobacterium* spp., and members of the *B. fragilis* group (two children).³²

DIAGNOSIS

As with other anaerobic infections, the diagnosis of infections caused by anaerobic gram-negative bacilli requires a high index of suspicion. For the most part, these infections must be suspected based on the clinical presentation and then diagnosed using microbiologic methods. When anaerobic infections are suspected, specimens for culture should be collected without contamination from the endogenous flora of adjacent mucous membranes. In general, acceptable specimens for anaerobic culture include blood; aspirates of normally sterile body fluids, abscesses, or deep wounds; and surgically obtained specimens. Optimum specimens include aspirates and tissue, not swabs. In the setting of pneumonia, specimens should be obtained via a protected brush or catheter.⁷ Gram-stained smears of aspirated material should be examined and interpreted in the context of culture results.

Specimens submitted for anaerobic culture should be rapidly transported to the laboratory in anaerobic transport devices and promptly inoculated into appropriate media in an oxygen-free environment (e.g., anaerobic jar or glove box). Media that support cultivation of anaerobes are supplemented with reducing substances (e.g., thioglycolate, dithiothreitol, cysteine, iron shavings, or chopped meat) and antibiotics to suppress the growth of facultative bacteria. Even before inoculation, such media must be prepared and stored under anaerobic conditions to prevent generation of superoxide or hydrogen peroxide.^{42,102,130} In one hospital, improvements in techniques for recovery of anaerobes (i.e., media and transport conditions) and education of clinicians and microbiologists were associated with dramatic reductions in health care costs and mortality among patients with anaerobic infections.⁶

Bacterial isolates that grow anaerobically should be tested for aerotolerance to confirm whether they are obligate or facultative anaerobes. This process necessarily lengthens the time to reporting of culture reports to the clinician; however, the morphologic characteristics of certain anaerobes (e.g., *B. fragilis* group, pigmented *Prevotella* and *Porphyromonas* spp.) are sufficiently distinctive to allow preliminary reporting of presumptive results before aerotolerance testing, at least in experienced laboratories. Definitive identification of anaerobic isolates is performed using biochemical tests, gas-liquid chromatography of fermentation reaction products, direct immunofluorescence, molecular genetic methods, or a combination of these.^{42,130} At a minimum, anaerobic bacteria should be tested for the production of β -lactamase. Detailed antimicrobial susceptibility testing of anaerobes is possible using broth dilution, agar dilution, or E-test methods, but these procedures are not routinely performed in most hospital laboratories today.^{42,70,95,51} Recently, advances in molecular detection methods, especially polymerase chain reaction (PCR) technologies and 16S RNA gene sequencing, have

improved detection, identification, and quantitation of anaerobes. Sequence-based identification offers several advantages over culture-based methods, including improved accuracy over phenotypic identification and more rapid recognition of species.¹²⁴ Additionally, novel next-generation DNA sequencing technology is beginning to be available for clinical laboratories.¹¹⁴

TREATMENT

Appropriate therapy for anaerobic infections is both surgical and medical. In general, abscesses should be drained (and their contents sent for routine and anaerobic cultures). Debridement of necrotic tissue is critical to survival in severe infections such as necrotizing fasciitis.^{42,95} Hyperbaric oxygen has been used, in addition to debridement and antibiotics, in some children with clostridial myonecrosis or necrotizing fasciitis, but definitive recommendations as to its use cannot be made based on this limited experience.⁴²

Patients with anaerobic infections should promptly receive appropriate antibiotic therapy (Table 150.1). Delays in the initiation of antianaerobic therapy have been associated with increased morbidity, mortality, and duration of hospitalization in patients with severe infections involving anaerobes.⁶² In certain situations (e.g., peritonitis with a perforated viscus, brain abscess related to chronic mastoiditis), the clinician should assume that anaerobes are present and include agents active against these organisms in the initial antimicrobial regimen. For many anaerobic bacteria, there is no particular drug of choice, because many different antibiotics (alone or in combination) might be reasonable for a given patient. Because anaerobic infections often involve a mixed flora of aerobic and anaerobic bacteria, the selection of antimicrobial therapy must also take into account the likely aerobic bacteria involved in a given infection. Often it is this consideration that drives the selection of one antianaerobic drug over another, as in the choice of meropenem or piperacillin-tazobactam (active against most aerobic Enterobacteriaceae as well as *B. fragilis* group organisms and other anaerobes) over metronidazole (active against most anaerobes but inactive against aerobes) for treatment of a complicated intraabdominal infection. Other factors to consider include the toxicity, tolerability, tissue penetration, and cost of various available antibiotics.^{42,95}

Complicating matters, many anaerobic gram-negative bacilli have demonstrated increasing rates of resistance to penicillin, clindamycin, and other drugs in recent decades. Not surprisingly, resistance among anaerobic bacteria has been identified as a risk factor for clinical failure in the treatment of these infections.^{62,95} Because most hospital laboratories do not routinely perform antimicrobial susceptibility testing for

anaerobes, and because geographically relevant surveillance data on anaerobic susceptibility patterns are usually not available, clinicians often lack guidance (beyond that available in review articles and textbook chapters) as to the optimal selection of antibiotics for anaerobic infections in their patients.⁹³ Nonetheless, some general principles still apply. For example, aminoglycosides, monobactams (e.g., aztreonam), and older fluoroquinolones all have uniformly poor activity against anaerobes, whereas macrolides and older tetracyclines are only modestly more reliable. Several classes of antibiotics (see later discussion), traditionally considered as antianaerobic drugs, vary in their activity against different anaerobes, including *Bacteroides*, *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp. (see Table 150.1). Serious anaerobic infections should be treated with intravenous antimicrobial agents at maximum dosages to optimize their penetration into devitalized tissue and abscesses.^{42,57,71}

Penicillins and Penicillin/β-Lactamase Inhibitor Combinations

Penicillin G, ampicillin, and amoxicillin are active against most anaerobes that do not produce β-lactamase, including most isolates of *F. nucleatum*, *F. necrophorum*, and *Porphyromonas* spp. These drugs are less reliable against *Prevotella* spp. and virtually devoid of activity against *Bacteroides* spp. and thus should no longer be considered first-line agents for initial treatment of anaerobic infections in any body site. Their use should be limited to selected infections where source control has been achieved and involvement of β-lactamase-producing organisms (especially *B. fragilis* group members) has been excluded or where clinical suspicion of such organisms is low.

Combinations of penicillins with β-lactamase inhibitors, on the other hand, achieve broad-spectrum activity against anaerobic and aerobic bacteria, including anaerobic gram-negative bacilli. These agents are particularly well suited for treatment of intraabdominal infections, in which β-lactamase-producing gram-negative bacilli are uniformly present. A clinical practice guideline, published in 2010, endorses (among other options) the use of piperacillin-tazobactam for antimicrobial treatment of complicated intraabdominal infections in children.¹²³ Ampicillin-sulbactam and amoxicillin-clavulanate are active against most anaerobic and aerobic oropharyngeal flora and thus are suitable parenteral and oral antibiotics, respectively, for treatment of most anaerobic infections arising in the head, neck, and chest (although their use as single agents may be limited by their lack of activity against methicillin-resistant *S. aureus*). In recent years, increasing resistance to amoxicillin-clavulanate and piperacillin-tazobactam among *B. fragilis* group isolates has been noted in Europe, indicating that continued vigilance for emerging resistance to this class of antibiotics will be required.⁹⁵

TABLE 150.1 Percentages of Anaerobic Gram-Negative Bacilli Susceptible to Selected Antimicrobial Agents in Recent Reports

	<i>Bacteroides fragilis</i> group ^a	<i>Prevotella</i> spp. ^b	<i>Fusobacterium</i> spp. ^c	<i>Porphyromonas</i> spp. ^d
Penicillin G	0–13	16–69	85–100	74–100
Amoxicillin	0–21	55–88	80–100	88–100
Amoxicillin-clavulanate	82–90	93–100	89–100	100
Cefoxitin	60–90	93–100	91–100	95–100
Ceftriaxone	15–32	71–97	80–100	95–100
Chloramphenicol	97–100	100	96–100	
Clindamycin	48–80	62–97	85–100	90–100
Imipenem	94–100	94–100	92–100	100
Meropenem	92–100	99–100	92–100	100
Metronidazole	93–100	94–100	93–100	94–100
Moxifloxacin	52–89	71–88	80–88	96
Piperacillin-tazobactam	92–100	98–100	100	100
Tigecycline	73–100	100	100

Cephalosporins

First-generation cephalosporins have antianaerobic activity similar to that of penicillin G, and third-generation cephalosporins are only moderately more active. Ceftriaxone is active against most isolates of *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp., but most *B. fragilis* group isolates are resistant. The most active cephalosporins against anaerobes are the second-generation agents cefoxitin, cefotetan, and cefmetazole; of these, cefoxitin has the best activity against *B. fragilis* group members.⁴² Cefoxitin is recommended, among other options, as surgical prophylaxis for abdominal procedures involving entry into a hollow viscus and single-agent therapy for adults with community-acquired complicated intraabdominal infections of mild to moderate severity (but not for adults with severe disease or high-risk conditions).^{15,123} Increasing resistance to cefoxitin has been documented in recent years, however, suggesting that its use as monotherapy for intraabdominal infections should be approached with caution.⁹⁵ Cefoxitin remains useful for perioperative antimicrobial prophylaxis in surgical procedures involving the abdomen.¹⁶ Moreover, it is recommended as a first-line agent, in combination with doxycycline, for parenteral therapy for pelvic inflammatory disease.⁵⁵

Carbapenems

The carbapenems are parenterally administered β -lactams with broad coverage against both aerobes and anaerobes, including many cephalosporin-resistant gram-negative enteric pathogens. Because of this broad-spectrum activity, carbapenems are well suited for single-agent therapy for a variety of infections involving anaerobes, including complicated intraabdominal infections.¹²³ Resistance to carbapenems has been documented among *B. fragilis* group organisms but remains rare, affecting less than 2% of isolates in most surveys. Resistance is exceptionally rare among isolates of *Prevotella* and *Fusobacterium* spp., and such resistant isolates have not been observed in the United States. Of the available carbapenems, meropenem is the preferred agent for use in children, because it is less likely to induce seizures than imipenem-cilastatin.^{92,103}

Metronidazole

Metronidazole has excellent activity against anaerobic gram-negative bacilli, including *B. fragilis* group members that are frequently resistant to other classes of antibiotics. Resistance to this agent has begun to emerge among *B. fragilis* group strains and *Prevotella* spp. in the developing world and in Europe, but such isolates remain exceptionally rare in the United States.^{1,72,91,95,100,121} Of note, metronidazole is less reliable in its activity against many gram-positive anaerobes, and virtually all aerobic bacteria are inherently resistant to it. Because most anaerobic infections are polymicrobial, metronidazole is generally not used alone but in combination with other antibiotics active against aerobic bacteria. For example, a recent practice guideline lists combination therapy with metronidazole plus either cefepime, a third-generation cephalosporin, or an aminoglycoside (with or without ampicillin) as an appropriate antimicrobial strategy for therapy of complicated intraabdominal infections in children.¹²³ Among the many advantages of metronidazole are that it is generally well tolerated; penetrates well into many tissues, including those of the central nervous system; and can be administered orally.

Clindamycin

Over the past 2 decades, resistance to clindamycin has increased substantially among members of the *B. fragilis* group, with resistance rates exceeding 50% in some series.^{68,77,89,95} Because clindamycin is now less reliable than carbapenems, penicillin/ β -lactamase inhibitor combinations, or metronidazole against these organisms, it should no longer be considered a first-line agent for treatment of complicated intraabdominal infections. However, clindamycin continues to have good activity against most other anaerobic bacteria, including most strains of *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp. and gram-positive anaerobes. Thus, today clindamycin is better suited for treatment of infections involving oropharyngeal anaerobes than for those involving intestinal flora.

Clindamycin achieves comparable serum levels whether administered orally or intravenously and penetrates well into most tissues and fluids, including bones, joints, and abscesses. Clindamycin does not penetrate well into cerebrospinal fluid and thus should not be used for treatment of central nervous system infections.⁵⁷ For treatment of polymicrobial infections, clindamycin should be combined with a β -lactam or other antibiotic active against aerobic gram-negative bacilli (e.g., *Pasteurella multocida* in animal bite wounds or *Eikenella corrodens* in human bite wounds). Although clindamycin has traditionally been particularly associated with *Clostridium difficile*-induced pseudomembranous colitis, many other antibiotics can also induce this complication.⁴²

Quinolones

In contrast to earlier generations of fluoroquinolones, newer agents such as moxifloxacin possess significant in vitro activity against many anaerobic bacteria.^{63,72} Unfortunately, resistance to moxifloxacin among *B. fragilis* group organisms rapidly emerged in the late 1990s, and has continued to increase globally, thereby limiting the usefulness of newer quinolones for treatment of complicated intraabdominal and other anaerobic infections.^{10,69,95} However, a recent pooled analysis with four well controlled clinical trials published in 2013 evaluated the use of moxifloxacin for the treatment of adults with complicated intraabdominal infections. Of the pretherapy anaerobes from the moxifloxacin-treated group, 561 (87.4%) were susceptible at 2 mg/L or less, 34 (5.3%) were intermediate at 4 mg/L, and 47 (7.3%) were resistant at 8 mg/L or more. Moxifloxacin achieved similar clinical success rates against all anaerobes, including those isolated from patients infected with *Bacteroides fragilis*, *Bacteroides thetaiotaomicron*, and *Clostridium* species. For all anaerobes combined, the clinical success rate was 83.1% (466 of 561 patients) for a minimum inhibitory concentration (MIC) of 2 mg/L or less, 91.2% (31 of 34 patients) for an MIC of 4 mg/L, 82.4% (14 of 17 patients) for an MIC of 8 mg/L, 83.3% (5 of 6 patients) for an MIC of 16 mg/L, and 66.7% (16 of 24 patients) for an MIC of 32 mg/L or greater.⁷³ These results suggest that moxifloxacin can be considered for the treatment of mild to moderate intraabdominal infections.³¹ Moxifloxacin's activity against other anaerobic gram-negative bacilli has not been as well studied, but available data suggest that resistance occurs among a substantial minority of *Prevotella* and *Fusobacterium* spp. isolates.

Therapeutic advantages of the quinolones include their wide distribution in tissues and fluids and their good absorption after oral administration.¹⁰⁴ Newer quinolones may provide options for treating anaerobic infections in selected children, such as older adolescents. Nonetheless, the quinolones' role in pediatrics remains limited because concern lingers over their potential toxicity, because other agents with established safety profiles have equal or better activity against anaerobes, and because bacterial resistance to quinolones will likely continue to rise, owing to their continued widespread use in adults.

Tetracyclines

Most *B. fragilis* group organisms are resistant to tetracycline, as are a substantial proportion of *Prevotella* and *Fusobacterium* spp. isolates. Tigecycline is a newer antibiotic, belonging to the glycylcycline class, which has vastly improved activity against anaerobic gram-negative bacilli. Tigecycline is listed, among other options, as an appropriate single-agent therapy for adults with community-acquired complicated intraabdominal infections of mild to moderate severity (but not for adults with severe disease or high-risk conditions).¹²³ However, a recent meta-analysis of randomized controlled trials revealed that tigecycline is associated with increased mortality compared to other antimicrobial regimens.¹⁴⁴ Tigecycline's safety and efficacy in children have not been established. Additionally, *Pseudomonas aeruginosa* has been identified in up to 35% of children with intraabdominal infections, and more than 90% of *Pseudomonas* strains are resistant to tigecycline.^{123,125} In addition, the high rates of gastrointestinal side effects (e.g., pancreatitis) associated with this drug will likely limit its use in pediatric patients.⁶¹

Oxazolidinones

Linezolid possesses surprisingly good in vitro activity against anaerobic gram-negative bacilli. In a study of isolates in Belgium from 2003 through 2005, susceptibility rates to linezolid were 99% among *B. fragilis* group

members, 98% among *Prevotella* spp., and 100% for *Fusobacterium* spp.¹⁴¹ In another study from Germany, 100% of 80 *Fusobacterium* isolates were susceptible to linezolid.⁵⁹ Moreover, earlier studies also found overall excellent activity of oxazolidinones against many types of anaerobic bacteria, including *B. fragilis* group members.^{8,58,105,143} Although experience with the clinical use of this agent for anaerobic infections is limited, a case report described microbiologic cure and clinical improvement with linezolid therapy in a patient with sepsis caused by a *B. fragilis* strain resistant to metronidazole, penicillin/ β -lactamase inhibitors, carbapenems, and tetracyclines.¹³⁷ In another patient, an extensive soft tissue infection of the leg with *B. fragilis* resistant to clindamycin, metronidazole, cefoxitin, carbapenems, piperacillin-tazobactam, and tigecycline was successfully cured after combination therapy with linezolid and moxifloxacin.¹²⁰ The role of linezolid in therapy for complicated anaerobic infections merits further investigation.

PREVENTION

The prevention of infections caused by *Bacteroides*, *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp. hinges on measures that serve to limit the introduction of these bacteria into healthy tissues. Such methods include, but are not limited to, cleaning and debriding wounds properly, removing foreign bodies promptly, maintaining good dental and oral hygiene, avoiding disruption of the intestinal wall during surgery, appropriately prescribing perioperative antibiotic prophylaxis, and following recommendations for prevention of nosocomial pneumonia.^{16,17,42,54}

Acknowledgment

We thank Dr. Steven C. Buckingham for his extensive contributions to this chapter in previous editions of this text.

Classification and Nomenclature of Viruses

151

Marjorie J. Miller

Viruses originally were differentiated from other microorganisms by their small size and their filterability. Initial efforts to classify viruses were based on disease, pathogenesis, organ tropisms, and epidemiologic characteristics rather than on physicochemical properties of the virus particle. During the 1950s and 1960s, many new viruses were being discovered while evidence of virus structure and composition also was emerging, thereby prompting proposals that viruses be grouped on the basis of shared virion properties. The herpesvirus,¹ myxovirus,² and poxvirus⁶ groups were among the first taxonomic groups delineated. As more information concerning the physicochemical characteristics of viruses accumulated, the need for a universal system of classification and nomenclature became apparent.

The International Committee on Nomenclature of Viruses was established in 1966 at the International Congress of Microbiology in Moscow, some 20 years after a bacterial taxonomy first was published and 75 years after the discovery of viruses. In 1973, the International Committee on Nomenclature of Viruses became the International Committee on Taxonomy of Viruses (ICTV), which operates under the auspices of the Virology Division of the International Union of Microbiological Societies. The ICTV classifies viruses isolated from vertebrates, invertebrates, plants, fungi, protozoa, bacteria, and mycoplasmas and publishes periodic reports summarizing the most recent developments in viral taxonomy.^{5,7,8,10,11,13,17–19} Interim updates were published in *Intervirology* and more recently in *Archives of Virology*. The most updated information on virus taxonomy can be accessed through the Internet (<http://www.ICTVonline.org> and <http://www.ncbi.nlm.nih.gov>).

The hierarchical levels of virus taxonomy consist of order, family, subfamily, genus, and species and are based on the structural, physicochemical, biologic, and replicative properties of viruses.¹³ Structural characteristics include size, shape, presence or absence of an envelope, and capsid symmetry. Physicochemical characterization is based on type, strandedness, and the number of segments of nucleic acid, as well as the number and size of proteins and their functional activities. Biologic properties include host range, serologic relationships, pathogenicity, and transmission; replicative properties include nucleic acid replication, transcription, and translation.

Virus orders comprise groups of families that share common characteristics (e.g., biochemical composition, viral replication strategy, particle structure, and general genomic organization) distinguishable from those of other orders and families. Virus orders are designated with the suffix *-virales*. Currently, the ICTV has approved six orders, four comprising viruses affecting humans: *Herpesvirales*, family *Herpesviridae*; *Mononegavirales*, which includes the families *Paramyxoviridae*, *Rhabdoviridae*, and *Filoviridae*; *Nidovirales*, which comprises the families *Coronaviridae* and *Arteriviridae*; and *Picornavirales*, family *Picornaviridae*.

Virus families represent groups of genera that share common characteristics distinct from those of other families. Virus families are designated with the suffix *-viridae*. Most families have unique virion morphology, genome structure, or strategies of replication (Fig. 151.1). Virus subfamilies are designated with the suffix *-virinae* and have been introduced in seven families: *Coronaviridae* (*Coronavirinae*, *Torovirinae*), *Herpesviridae* (*Alphaherpesvirinae*, *Betaherpesvirinae*, *Gammaherpesvirinae*), *Paramyxoviridae* (*Paramyxovirinae*, *Pneumovirinae*), *Parvoviridae* (*Parvovirinae*), *Poxviridae* (*Chorodopoxvirinae*), *Reoviridae* (*Sedoreovirinae*, *Spinareovirinae*), and *Retroviridae* (*Orthoretrovirinae*, *Spumaretrovirinae*) (Table 151.1).

Virus genera consist of groups of species that share common characteristics different from those of members of other genera. Common properties within a genus include viral replication strategy, genome size, organization, numbers of segments, sequence homologies, and vector transmission. Virus genera are designated with the suffix *-virus*.

The species taxon is the most fundamental unit in biologic classification, but the viruses have proved to be the most difficult to classify, and years elapsed before a definition of virus species was accepted internationally. In 1991, the ICTV accepted the definition of a virus species proposed by van Regenmortel¹⁴: “A virus species is defined as a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche.” Members of a polythetic class have several properties in common, although no single common attribute is present in all members, thereby accommodating the inherent variability of viruses. Common species properties include genome rearrangement, sequence homologies, serologic relationships, vector transmission, host range, pathogenicity, tissue tropism, and geographic distribution.^{8,17} Some properties of viruses used in taxonomy are listed in Box 151.1.¹³

The ICTV also has established criteria for formal virus nomenclature^{8,9,17} and recommended abbreviations for virus names.^{4,8,9,17} In formal taxonomic usage, the names of orders, families, subfamilies, genera, and species are printed in italics, and the first letter of the name is capitalized. This form applies when using a species name to refer to a taxonomic category (e.g., in the Materials and Methods section of a paper when describing the particular virus used in the study). Some examples of formal taxonomic terminology are *Poliovirus*, genus *Enterovirus*, family *Picornaviridae* or *Human herpesvirus 1* (herpes simplex virus type 1) and genus *Simplexvirus*, subfamily *Alphaherpesvirinae*, family *Herpesviridae*. Thereafter, vernacular names can be used throughout the publication. In informal vernacular usage when referring to virions or virus particles or if used as an adjective, italics and capital initial letters are not required and the names are written in lowercase Roman script (e.g., “poliovirus cytopathic effect” or “picornaviruses/polioviruses were inoculated into cell culture”).^{8,9,15,16} Viruses with uncertain taxonomic status are considered “tentative” species, and names are not italicized, although the initial letter is capitalized. Although not part of the formal international code, abbreviations also have been recommended by the ICTV for every virus name to reduce the possibility of duplication when new abbreviations are proposed^{4,8,17} (see Table 151.1).

Fig. 151.2 is a schematic diagram showing the basic forms and composition of viruses.³ The type of nucleic acid, capsid symmetry, presence or absence of an envelope, and peplomers (spikes) all are characteristics used in classification. Fig. 151.1 is a more detailed diagram not only illustrating the relative shapes and sizes of families and genera of vertebrate viruses but also indicating the type and nature (single-stranded [ss], double-stranded [ds], sense [+/-]) of the nucleic acid, presence of reverse transcriptase (RT), and presence or absence of an envelope.

Fig. 151.3 and Fig. 151.4 show classification of DNA and RNA virus families,¹² respectively, by some of the taxonomic characteristics listed in Box 151.1. Representative DNA and RNA viruses affecting humans are listed in Table 151.1, which uses the most recent nomenclature reported by the ICTV (for a complete listing, see King and colleagues⁸).

San Diego, CA: Academic Press; 2000:30.)

TABLE 151.1 Classification and Nomenclature of Representative Viruses Affecting Humans

Family	Subfamily	Genus	Representative Species Pathogenic for Humans (Abbreviation, Common Examples, Disease, Synonym, or No. of Members)		
DNA Viruses					
Poxviridae	Chordopoxvirinae	Orthopoxvirus	Vaccinia virus (VACV) Variola virus (VARV)		
		Parapoxvirus	Orf virus (ORFH, contagious pustular dermatitis) Pseudocowpox virus (PCPV, milker's nodule)		
		Molluscipoxvirus	Molluscum contagiosum virus (MOCV)		
		Yatapoxvirus	Yaba monkey tumor virus, tanapox virus (YMTV, TANV)		
Herpesviridae	Alphaherpesvirinae	Simplexvirus	Human herpesvirus 1 (HHV-1, herpes simplex virus type 1) Human herpesvirus 2 (HHV-2, herpes simplex virus type 2) Macacine herpesvirus 1 (McHV-1, monkey B virus)		
		Betaherpesvirinae	Varicellovirus	Human herpesvirus 3 (HHV-3, varicella-zoster virus)	
	Cytomegalovirus		Human herpesvirus 5 (HHV-5, cytomegalovirus)		
	Roseolovirus		Human herpesvirus 6A and 6B (HHV-6, human B lymphotropic virus) Human herpesvirus 7 (HHV-7)		
	Gammaherpesvirinae	Lymphocryptovirus	Human herpesvirus 4 (HHV-4, Epstein-Barr virus)		
		Rhadinovirus	Human herpesvirus 8 (HHV-8, Kaposi sarcoma-associated herpesvirus)		
	Adenoviridae		Mastadenovirus	Human mastadenovirus A (HAdV-A; 12, 18, 31) Human mastadenovirus B (HAdV-B; 3, 7, 11, 14, 16, 21, 34, 35, 50, 55) Human mastadenovirus C (HAdV-C; 1, 2, 5, 6, 57) Human mastadenovirus D (HAdV-D; 8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51, 53, 54, 56) Human mastadenovirus E (HAdV-E; 4) Human mastadenovirus F (HAdV-F; 40, 41) Human mastadenovirus G (HAdV-G; 52)	
			Papillomaviridae	Alphapapillomavirus	Alphapapillomavirus 7 (HPV 18, 39, 45, 59, 68, 70, 85, 97) Alphapapillomavirus 9 (HPV 16, 31, 33, 35, 52, 58, 67)
Betapapillomavirus				Betapapillomavirus 1 (HPV 5, 8, 12, 14, 19–21, 25, 36, 47, 93)	
Gammapapillomavirus				Gammapapillomavirus 1 (HPV 4, 65, 95)	
Polyomaviridae				Polyomavirus	BK polyomavirus (BKPv, polyomavirus hominis 1) JC polyomavirus (JCPv, polyomavirus hominis 2)
Parvoviridae			Parvovirinae	Bocaparvovirus	Human bocavirus (HBoV)
				Erythroparvovirus	Human parvovirus B19 (B19V, erythema infectiosum or fifth disease)
Hepadnaviridae		Orthohepadnavirus	Hepatitis B virus (HBV)		
Hepeviridae		Hepevirus	Hepatitis E virus (HEV, enterically transmitted non-A, non-B)		
RNA Viruses					
Reoviridae	Sedoreovirinae	Orbivirus	Changuinola virus (CGLV); Great Island virus (GIV)		
		Rotavirus	Rotavirus A–H (RV)		
	Spinarevirinae	Coltivirus	Colorado tick fever virus (CTFV)		
Bornaviridae		Bornavirus	Borna disease virus (BDV)		
Paramyxoviridae	Paramyxovirinae	Henipavirus	Hendravirus, Nipahvirus		
	Pneumovirinae	Morbillivirus	Measles virus (MeV)		
		Respirovirus	Human parainfluenza virus 1 and 3 (HPIV-1, HPIV-3)		
		Rubulavirus	Mumps virus (MUV), human parainfluenza virus 2 (HPIV-2) and 4 (HPIV-4a and b)		
		Pneumovirus	Human respiratory syncytial virus (HRSV)		
		Metapneumovirus	Human metapneumovirus (HMPV)		
Rhabdoviridae		Vesiculovirus	Vesicular stomatitis Indiana virus (VSV)		
		Lyssavirus	Rabies virus (RABV)		
Filoviridae		Marburgvirus	Marburg marburgvirus (LMARV, Lake Victoria)		
		Ebolavirus	Zaire ebolavirus (ZEBOV), Reston ebolavirus (REBOV)		
Orthomyxoviridae		Influenzavirus A	Influenza A virus (FLUAV)		
		Influenzavirus B	Influenza B virus (FLUBV)		
		Influenzavirus C	Influenza C virus (FLUCV)		
Bunyaviridae		Orthobunyavirus	Bunyamwera virus (BUNV, Bunyamwera serogroup), California encephalitis virus (CEV, California serogroup) (mosquito and culicid fly transmitted)		
		Hantavirus	Hantaan virus (HTNV, Korean hemorrhagic fever or hemorrhagic fever with renal syndrome), Sin Nombre virus (SNV, Four Corners hantavirus, hantavirus pulmonary syndrome), and others (rodent associated)		
		Nairovirus	Crimean-Congo hemorrhagic fever virus (CCHFV; tick transmitted)		
		Phlebovirus	Sandfly fever Naples virus (SFNV), Rift Valley fever virus (RVFV) (sandfly-borne primarily); Uukuniemi virus (UUKV) (phlebotomine, tick, and mosquito transmitted)		
Arenaviridae		Mammarenavirus	Lymphocytic choriomeningitis mammarenavirus (LCMV) Lassa mammarenavirus (LASV) Junin mammarenavirus (JUNV, Argentine hemorrhagic fever virus) Machupo mammarenavirus (MAVC, Bolivian hemorrhagic fever virus)

TABLE 151.1 Classification and Nomenclature of Representative Viruses Affecting Humans—cont'd

Family	Subfamily	Genus	Representative Species Pathogenic for Humans (Abbreviation, Common Examples, Disease, Synonym, or No. of Members)
<i>Picornaviridae</i>		<i>Aphthovirus</i>	Foot-and-mouth disease virus
		<i>Enterovirus</i>	Enterovirus A (EV-A, 25 serotypes; coxsackieviruses A2, 8, 10, 12, 14, 16; enterovirus A 71, 76, 89–92, 114, 119–121) Enterovirus B (EV-B, 63 serotypes; coxsackieviruses B1–B6; coxsackievirus A9, 23; echovirus 1–21, 24–27, 29–33; enterovirus B, 28 serotypes) Enterovirus C (EV-C, 23 serotypes; coxsackieviruses A1, 11, 13, 17, 19–22, 24; PV, polioviruses 1–3; human enterovirus C, 11 serotypes) Enterovirus D (EV-D, 5 serotypes; enterovirus D68, 70, 94, 111, 120) Rhinoviruses A, B, and C (RV-A, B, C; 167 serotypes) Parechovirus A (HPeV, 1–16; human parechovirus 1, formerly echovirus 22; human parechovirus 5, formerly echovirus 23) Hepatovirus A (HAV, enterovirus 72)
		<i>Parechovirus</i>	
		<i>Hepatovirus</i>	
<i>Caliciviridae</i>		<i>Norovirus</i>	Norwalk virus (NoV, genogroups I, II, IV; >25 genotypes)
		<i>Sapovirus</i>	Sapporo virus (SaV, genogroups I, II, IV, V)
<i>Astroviridae</i>		<i>Mamastrovirus</i>	Mamastrovirus 1, 6, 8, 9 (MAstV)
<i>Coronaviridae</i>	<i>Coronavirinae</i>	<i>Alphacoronavirus</i>	Human coronavirus 229E (HCoV-229E); human coronavirus NL63 (HCoV-NL63)
		<i>Betacoronavirus</i>	Human coronavirus HKU1 (HCoV-HKU1); human coronavirus OC43 (HCoV-OC43); severe acute respiratory syndrome–related virus (SARS-CoV); Middle East respiratory syndrome (MERS-CoV)
<i>Flaviviridae</i>		<i>Flavivirus</i>	St. Louis encephalitis virus (SLEV), yellow fever virus (YFV), dengue virus (DENV), and West Nile virus (WNV), Zika virus (ZIKV) group B arboviruses (mosquito-borne) Kyasanur Forest disease virus (KFDV), tick-borne encephalitis virus (TBEV) (tick-borne) Vector-unassociated viruses Hepatitis C virus (HCV, parenterally transmitted non-A, non-B hepatitis)
		<i>Hepacivirus</i>	
<i>Togaviridae</i>		<i>Alphavirus</i>	Western, Eastern, and Venezuelan equine encephalitis viruses (WEEV, EEEV, VEEV); Ross River and Sindbis viruses (RRV, SINV; group A arboviruses, mosquito-borne)
		<i>Rubivirus</i>	Rubella virus (RUBV)
<i>Retroviridae</i>	<i>Orthoretrovirinae</i>	<i>Deltaretrovirus</i>	Primate T-cell lymphotropic viruses 1–3 (simian T-lymphotropic viruses, STLV 1–3; human T-lymphotropic viruses, HTLV 1–3)
		<i>Lentivirus</i>	Human immunodeficiency viruses 1 and 2
Subviral Agents (Satellites, Viroids, and Agents of Spongiform Encephalopathies)			
Prions			Kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome (GSS), fatal familial insomnia (FFI)
Unclassified Viruses			
		<i>Deltavirus</i>	Hepatitis delta virus (HDV)

BOX 151.1 Representative Properties Used in Virus Taxonomy

Virion Properties

Size
Shape
Presence, absence of envelope and peplomers
Capsid structure, symmetry

Physical Properties

Molecular mass
Buoyant density
Sedimentation coefficient
pH stability
Thermal stability
Solvent, detergent stability
Cation (Mg²⁺, Mn²⁺) stability
Radiation stability

Genome

Type of nucleic acid, DNA or RNA
Strandedness, single- or double-stranded
Linear or circular
Sense: positive, negative, or ambisense
Number of segments
Size
Presence or absence and type of 5' terminal cap
Nucleotide sequence comparisons

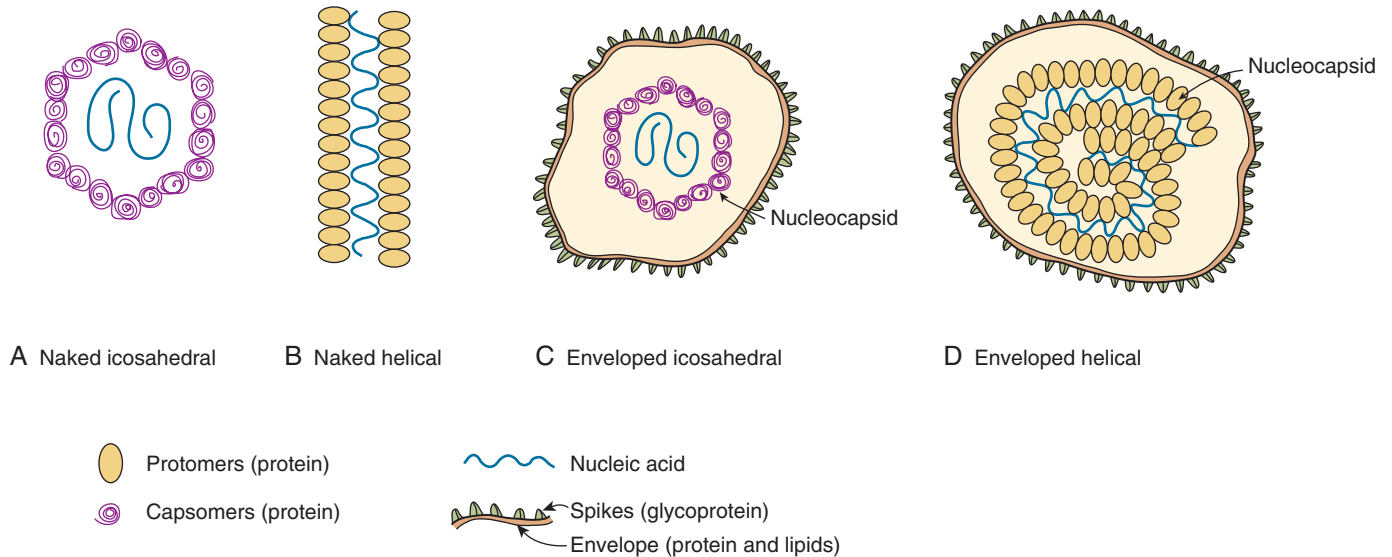

FIG. 151.2 Simple forms of virions and their components. The naked icosahedral virions resemble small crystals; the naked helical virions resemble rods with a fine regular helical pattern in their surface. The enveloped icosahedral virions are composed of icosahedral nucleocapsids surrounded by the envelope; the enveloped helical virions are helical nucleocapsids bent to form a coarse, often irregular, coil within the envelope. (From Davis BD, Dulbecco R, Eisen HN, et al. *Microbiology*. 4th ed. Philadelphia: JB Lippincott; 1990:772.)

Characteristic	Classification			
Nucleic acid core	DNA

SUBSECTION I DNA—*Parvoviridae*

152

Human Parvovirus B19

Danica J. Schulte

The family *Parvoviridae* includes two subfamilies: *Parvovirinae* and *Densovirinae*.^{353,482} The subfamily *Parvovirinae* has six genera: Erythrovirus, Parvovirus, Dependovirus, Bocavirus, Amdovirus, and Parv4; the subfamily *Densovirinae* has five genera: Brevidensovirus, Pefudensovirus, Densovirus, Iteravirus, and Centrovirus. Densovirinae viruses (*Densovirus* spp.) infect insect hosts and have not been found in humans or mammals,^{37,391} whereas the *Parvovirinae* are viruses of vertebrates.⁵⁴

Currently, human parvovirus B19 is the only member of the genus *Erythrovirus* that infects humans; however, two other genera of the subfamily *Parvovirinae* (Parv4 and Bocavirus) also cause human infection.⁴⁴⁴ Originally, B19 virus was classified in the genus *Parvovirus*. Despite the reclassification, the contemporary literature still refers to this Erythrovirus as parvovirus B19. This virus is autonomous and does not require the presence of a helper virus.

erythema infectiosum,
fifth disease,
slapped cheek

Three human parvovirus B19 genotypes have been defined based on isolates with greater than 10% divergence in overall DNA sequence, all causing human disease.^{54,416} In 1999, Erythrovirus V9, a member of genotype 3, was found to be clinically significant.^{194,198,200,382,443} V9 virus was found in the serum and bone marrow of a 6-year-old boy with transient aplastic anemia³⁶⁰; however, routine testing for B19 virus failed to identify the V9 virus¹⁹⁴ because it has more than 11% variation from the published B19 genome, with nucleotide discrepancies encompassing the entire genome.^{198,200,444}

B19 typically is well conserved, with less than 2% sequence variability among isolates.^{198,200,360,484} The prevalence of each genotype varies with geographic origin, population, and sample type. Genotype 1 is present worldwide, whereas genotype 3 is prevalent in Africa, and genotype 2^{139,444,546} primarily circulates in Europe and North America and is very limited.^{170,444}

More recently, two additional members of the *Parvovirinae* subfamily have been discovered. One of these, human bocavirus, is discussed in Chapter 153. The other virus, Parv4, was found in plasma samples from pooled plasma collections,^{159,300,473} placentally,⁸⁰ and in persons screened for acute human immunodeficiency virus (HIV) infection.^{231,312}

Erythema infectiosum is the most common clinical manifestation of infection with parvovirus B19. Other clinical findings include arthralgia and arthritis, aplastic crisis in patients with red blood cell defects, chronic anemia in immunocompromised patients, fetal hydrops, cardiac disease, neurologic disease, and a variety of other significant illnesses.

HISTORY

The first parvoviruses to be discovered infecting humans were found in stool specimens by electron microscopy.³⁹² These fecal parvoviruses have been linked with gastrointestinal symptoms, often in outbreaks associated with the consumption of shellfish.^{123,491} Their precise pathogenic role remains unclear because these viruses also may be found in the feces of asymptomatic individuals.³⁹²

In 1974, a second type of parvovirus, human parvovirus B19, was found in the serum of asymptomatic blood donors.^{54,104,194} Discovered by chance as an agent responsible for false-positive results in the counterimmunoelectrophoresis tests then in use for detection of hepatitis B surface antigen, it was revealed by electron microscopy to be uniform icosahedral particles with a mean diameter of 23 nm.

Preliminary studies of the physiochemical nature of this agent suggested its probable identity as a member of the family *Parvoviridae*.¹⁰⁴ In the following years, reports concerning this virus named it variously as human parvovirus-like agent, serum parvovirus-like virus,⁹⁶ and B19⁴⁵⁰ after one of the original isolates. After its chemical properties were elucidated in 1983,^{91,469} the virus was referred to as human parvovirus—or human serum parvovirus—to denote that it is distinct from the fecal viral particles. Today, the virus most commonly is called human parvovirus B19 or simply B19 virus.^{9,97,247}

For many years after its discovery, infection with B19 virus appeared to be either asymptomatic or associated with a nonspecific febrile illness.⁴⁵⁰ However, in the early 1980s, the central role of B19 virus in the etiology of aplastic crisis in patients with chronic hemolytic anemia was identified.^{87,122,236,412,442} Soon thereafter came the appreciation that erythema infectiosum (fifth disease) is the common manifestation of infection with B19 virus.¹⁶ Over 20 years ago, the association between B19 virus infection in pregnancy and fetal death was observed; during the past few decades, the clinical spectrum of B19 virus infection has broadened considerably.*

Although human parvovirus B19 was not discovered until 1974, its most common clinical disease (erythema infectiosum) was described more than 200 years ago.⁴⁸ Tschamer's report in 1889 was considered by most reviewers to be the first description of erythema infectiosum.⁴⁸⁷ However, Boysen⁴⁸ noted that the English dermatologist Robert Willan had reported the illness first in 1799 and then more completely in 1840.

After Tschamer's report came a succession of Austrian and German reports of the illness.⁴⁸ Tschamer thought that erythema infectiosum was a manifestation of rubella, but a few years later Escherich¹⁴¹ suggested that it was a specific disease. Stricker,⁴⁶⁷ in 1899, gave the name erythema infectiosum to the clinical entity.

In 1905, Shaw,⁴⁴⁹ after having observed cases of erythema infectiosum in Austria, published the first account in the American literature. Herrick²⁰⁶ was the first to document in detail an outbreak in the United States; however, cases of erythema infectiosum had been observed previously in St. Louis⁵⁵¹ and in Hamburg, New York.²⁰⁶ Over the past century, numerous outbreaks and epidemics have been described in North America.* Erythema infectiosum frequently is referred to as fifth disease; in the past, it also was called ring rubella, large-spotted disease, and epidemic megalooerythema.

PROPERTIES OF THE VIRUS

Human parvovirus B19 is a naked icosahedral virus with a mean diameter of 23 nm and a mean buoyant density in cesium chloride of 1.43 g/dL.¹⁰⁴ The capsid is formed from two major structural proteins (VP1 and VP2) discernible by sodium dodecyl sulfate–polyacrylamide gel electrophoresis.⁹¹ VP2 is the major structural protein, with a molecular weight of 58 kDa; VP1 has a molecular weight of 84 kDa. A total of 96% of the capsid is VP2, and 4% is VP1. The structure of VP2 has been determined by x-ray crystallography.^{194,234} The major nonstructural protein (NS1) has a molecular weight of 77 kDa and acts as a strong transcription activator by recruiting cellular transcription factors and participating in viral replication.⁴⁴⁴

The genome consists of a single molecule of single-stranded DNA approximately 5.6 kb in length.¹¹² The DNA in B19 virus occurs as both plus and minus strands in approximately equal numbers.²³⁸ When virions are disrupted with protease, the two complementary strands anneal to form a stable duplex.⁴⁶⁹ At each end of the molecule are palindromic sequences forming hairpin loops. The hairpin at the 3' end of the genome serves as a primer for DNA polymerases. The hairpin duplex at the 5' end of the molecule consists of sequences that are neither complementary to those at the 3' end, as is found in dependoviruses, nor as highly complementary within this 5' end as are those at the 3' end.⁷² Folding of the VP1 and VP2 proteins creates α -helical loops that appear on the surface of the capsid and are available to the host immune system. The unique region of VP1 is external to the capsid; it contains linear epitopes recognized by neutralizing antibodies and elicits a more efficient immune response than the VP2 region,⁵⁴⁶ but antibodies against the VP2 capsid protein are maintained.⁹⁸ NS1 can activate tumor necrosis factor- α , interleukin-6, nuclear factor κ B, and TP53 and influences signaling pathways involved in the antiviral response.⁹⁸ Moreover, B19 DNA can activate Toll-like receptor 9 into erythroid cells, leading to inhibition of cell growth.⁴⁴⁴

Parvovirus infectivity is relatively heat stable, tolerant of a wide range of pH, and resistant to ether.¹⁹ Successful replication of parvoviruses can be accomplished only in a dividing cell because of the absolute requirement for the host-cell function or functions found in late S phase.¹⁹⁰ Human parvovirus B19 can be propagated only in human erythropoietic cells from bone marrow, erythroid cells from a patient with erythroleukemia, human umbilical cord, and peripheral blood and in primary fetal liver culture.^{58,194,238,386,391,462,463,476} It grows only in dividing cells; therefore, all the aforementioned tissue culture systems require the addition of erythropoietin and are regulated by STAT5A and MEK signaling.⁷⁹

The cellular receptor for B19 virus infection is the blood group P antigen, which is a globoside and a neutral glycolipid.⁵⁵ The P antigen also requires a cellular coreceptor, $\alpha_5\beta_1$ integrin, for sufficient entry of parvovirus B19 into human cells.⁵¹⁷ In cooperation with P antigen, B19 virus can also bind to Ku80 autoantigen, expressed on B and T lymphocytes, to mediate efficient cell entry.⁹⁸ P antigen is found on erythroblasts, megakaryoblasts, endothelial cells, and fetal myocytes.⁵⁵ People who lack P antigen are resistant to infection with B19 virus, and

*References 8, 42, 83, 194, 197, 210, 238, 239, 352, 397, 434, 439, 528, 546.

*References 3, 20, 24, 25, 30, 50, 70, 78, 89, 93, 99, 125, 153, 158, 166, 173, 194, 249, 283, 284, 296, 333, 354, 398, 399, 413, 453, 506, 507, 522, 525, 546, 547.

in vitro studies demonstrate that the erythroid precursors from people lacking P antigen cannot be infected, even in the presence of high concentrations of virus.^{57,194,294}

Antigenically, this human erythrovirus is distinct from the parvovirus-like particles found in feces³⁹³ and from the human dependoviruses and autonomous animal parvoviruses.¹⁰⁴ However, the nucleotide sequence and hybridization results reported by Turton and associates⁴⁹¹ suggest that the viruses from gastroenteritis cases in 1977 and 1986 are similar to B19 virus. In contrast to animal parvoviruses, no hemagglutinin has been demonstrated.

The degree to which B19 virus is related to other mammalian parvovirus types has been investigated by DNA-DNA hybridization. Although no relationship is discernible with the human dependoviruses, a distant evolutionary relationship to the genomes of the autonomous parvoviruses of rodents is apparent. Interestingly, this relationship is closer than that between B19 virus and the parvoviruses infecting domestic animals (bovine, feline, and canine parvoviruses).¹⁰⁵ Shackelton and Holmes⁴⁴⁷ studied the evolutionary dynamics and phylogenetic history of the *Parvoviridae* and observed a high rate of evolutionary change, with 10^{-4} nucleotide substitutions per site per year.

Many recent studies have examined genetic variability in parvovirus B19 isolates.^{42,138,160,204,229,247} Hemauer and associates²⁰⁴ suggested that greater genome variability occurs in isolates from patients with persistent infection than in isolates from patients with acute infection. Erdman and colleagues¹³⁸ noted that geographically defined genetic lineages of parvovirus B19 existed but that no particular genotype was associated with a specific clinical manifestation.

EPIDEMIOLOGY

Outbreaks of erythema infectiosum have been observed throughout the world, but most reports have come from nontropical regions. The epidemic pattern of erythema infectiosum is surprisingly similar to that of rubella. Community epidemics are most prevalent in the winter and spring, and they usually last for 3 to 6 months. In a review of 30 well-described epidemics,^{*} 26 had their onset in the period from December through May and 23 of the 30 peaked in March, April, or May. When the North American literature for a 50-year period is examined, a cyclic pattern is evident, with peaks in disease activity occurring approximately every 6 years. The peak periods last for an average of 3 years. A longitudinal study of aplastic crisis in persons with sickle-cell anemia in Jamaica suggested that peaks in incidence occur every 2 to 3 years in that island population.⁴⁴²

The case-to-case interval of erythema infectiosum is reported to be between 4 and 14 days.^{3,16,125,173,404,506,525} In an epidemic in an elementary school, Greenwald and Bashe¹⁷³ noted that the mean case-to-case interval was 8.7 days. Ager and associates³ in their studies noted clustering of intervals between cases of 7 to 11 days. The data of Wilcox and Evans⁵²⁵ on multiple cases in households suggest that the case-to-case interval usually is closer to 12 to 14 days. In a volunteer study in which adults were inoculated intranasally, the incubation time until onset of the rash was 17 to 18 days.¹³ From this study, the case-to-case interval in the community would be expected to be between 6 and 12 days because shedding of virus occurs between days 5 and 12 of infection. This prediction accords well with intervals in the studies noted earlier, as well as intervals observed in patients with hematologic diseases and aplastic crisis.³⁴⁰

In epidemics, the attack rate is high. Lauer and colleagues²⁸³ noted an overall attack rate of 24.3% in schoolchildren in kindergarten through the eighth grade. Similar attack rates were noted in three other school-related outbreaks.^{125,168,173} In the community as a whole, the attack rate is highest in children 5 to 14 years of age,^{2,3} but secondary cases occur in preschool children, teachers, and parents. In the home, secondary cases are reported more commonly in mothers than in fathers.³ In school epidemics, the attack rate is considerably higher in girls than in boys.^{125,283} Prevalence studies of serum IgG antibody to B19 virus have noted that 40% to 60% of adults older than the age of 20 years, up to

85% of the elderly, and only 2% to 21% of children younger than age 11 years are seropositive.^{9,17,15,444} The rate of transmission among household contacts is nearly 50%.⁴⁹⁶

Nosocomial infections do occur; most often, the index case is an unrecognized, chronically infected patient.^{2,269,401} During community outbreaks, the risk for acquisition by hospital workers is no greater than that in other community residents.

Although erythema infectiosum long had been postulated to be transmitted by droplet via the respiratory tract,³ proof of this route was not obtained until a group of volunteers were infected successfully with B19 virus after intranasal inoculation. One week after inoculation, virus was excreted from the respiratory tract for 6 days.¹³

The role of human leukocyte antigen (HLA) class I and II alleles was investigated by Kerr and associates²⁴² in northwestern England. Thirty-six patients with symptomatic B19 infection and 900 controls were studied. The frequency of HLA alleles DRB1*01, DRB1*04, and DRB1*07 was significantly higher in patients with B19 infection than in control subjects.

In a cohort study of 169 children with severe anemia in Papua New Guinea, a strong association between severe anemia and B19 infection was observed; however, the authors were unable to show a combined deleterious effect of malaria and B19 infection.⁵²² They and others demonstrated that 60% of the children were infected with B19 before reaching 2 years of age and that more than 90% were infected by 6 years of age.^{179,390,430,526}

Parvovirus B19 infection also can be transmitted by blood transfusion and clotting factor concentrates.* One case of transmission of B19 DNA via peripheral blood progenitor cell transplantation that resolved after treatment with intravenous immune globulin (IVIG) has been reported.¹⁸ Hayakawa and colleagues¹⁹¹ reported a case of parvovirus B19 infection that they thought was transmitted by IVIG. Researchers have described donor-transmitted parvovirus infection in transplant patients.⁵³⁵

PATHOGENESIS AND PATHOLOGY

The pathogenesis of erythroviral disease involves two quite separate components. The first is caused by the lytic infection of susceptible dividing cells and the second by interaction with products of the immune response.

As stated earlier, parvoviruses replicate only in dividing cells. Thus, infection of an organ or tissue in which a significant proportion of the cells are dividing may give rise to organ-specific disease. This condition is seen clearly in canine and feline parvovirus infections, in which replication of virus in the crypt cells of the intestine gives rise to a severe and often fatal enteritis.^{184,306}

Parvovirus B19 is thought not to infect cells of the gastrointestinal tract; virus could not be detected in the feces of volunteers,¹³ nor have viruses of this type been found in stool specimens.

After gaining entry via the respiratory tract, the virus sets up a systemic infection with copious viremia (Fig. 152.1) in which 10^{10} or 10^{11} virus particles per milliliter of blood is not an uncommon finding.^{13,406}

Parvovirus infection results in profound reticulocytopenia for some 7 to 10 days, commencing during viremia.^{13,546} In vitro studies on cultured bone marrow and peripheral blood have shown that B19 virus inhibits the formation of blast-forming erythroid colonies, thus suggesting that an early erythrocyte precursor cell is susceptible to infection with the virus. B19-associated damage to cells of the erythroid lineage is due to the cytotoxicity mediated by viral proteins, whereas the apoptotic features mediated by caspase 3 are induced by NS1.^{81,86} Overexpression of NS1 has been found to trigger signaling cascades that help promote proapoptotic and apoptotic processes, resulting in anemia, acute fulminant liver failure, placental insufficiency, and myocarditis.⁵³² In addition to profound erythroid hypoplasia, giant pronormoblasts typically are seen in the bone marrow at the height of transient aplastic crises and normoblasts have characteristic intranuclear eosinophilic inclusion bodies, termed *Lampion* or *lantern cells*.⁶³

FIG. 152.1 Selected virologic, immunologic, hematologic, and clinical events in parvovirus B19 virus infection.

Granulocytes and megakaryocytes are unaffected by virus in these *in vitro* systems. However, during B19 virus infection in a normal host, clinically insignificant lymphopenia and neutropenia occur, as does a drop in platelet number.^{13,404} The mechanisms of loss of these cells from peripheral blood remain to be determined. Srivastava and associates⁴⁶² noted that B19 virus infection of bone marrow cells in culture results in suppression of megakaryocyte colony formation. In this study, tropism of B19 virus for cells other than erythroid progenitor cells appeared to take place, although viral DNA replication did not occur in the megakaryocyte-enriched fractions. They suggested that the virus might be toxic to cell populations that are nonpermissive of viral DNA replication.

As noted in Fig. 152.1, viremia ends at the time of appearance of specific immunoglobulin M (IgM) antibody. In addition, researchers have found that the appearance of antibody neutralizes the inhibitory effect of B19 virus on formation of erythrocyte colonies *in vitro*.⁵⁴⁷ The early IgM response is almost entirely VP2 specific. IgG antibody first appears approximately 2 weeks after exposure and later becomes the major antibody subclass; in contrast to the initial IgM response, the IgG response is directed at VP1 rather than VP2. The role of cellular immunity in recovery from infection is unclear. Most patients with persistent infection have T-cell as well as other immune defects, thus suggesting a cellular component in the host response.⁴² Von Pöbltzki and associates⁵⁰⁴ showed that the T cells of persons with parvovirus B19 antibody had HLA class II–restricted responses against B19 structural proteins. Franssila and colleagues¹⁵⁶ demonstrated virus-specific helper T-cell proliferation in recently and remotely infected patients. Their data suggested that B cells that recognize the viral capsid (VP1 and VP2) receive class II–restricted help from CD4⁺ T lymphocytes. While investigating a parvovirus B19 vaccine, this same group demonstrated that VP1 contains important B-cell epitopes required for protective B-cell immunity; they concluded that VP2, the major structural protein of B19 virus, appears to provide the major target for B19-specific helper T cells years or decades after initial infection occurs.^{154,155} A persistent, activated B19-specific CD8⁺ T-cell repertoire with maintained effector function occurs in healthy patients who successfully clear the B19 virus. Researchers have hypothesized that these activated CD8⁺ T cells may play a prominent role in controlling acute B19 infection.^{222,233,297,370} Additionally, Kerr and colleagues^{240,245} reported that circulating cytokine and chemokine levels in acute B19 disease may correlate with clinical disease.

The most common result of infection with B19 virus is erythema infectiosum. Fig. 152.1 shows that the symptoms of this disease begin 17 or 18 days after inoculation and that approximately 1 week after inoculation virus can be detected in either throat swabs or blood. Skin biopsy results have been reported in three studies.^{30,174,212} In three skin

biopsy specimens from regions of reticulated eruption, Bard and Perry³⁰ noted either normal skin or very mild inflammatory changes. Hoffman²¹² described edema in the epidermis and perivascular infiltration with mononuclear cells; he also noted swelling of the endothelium of superficial vessels and the presence of cleavage spaces between the epidermis and dermis. The histopathology in 10 cases was investigated by Grimmer and Joseph.¹⁷⁴ They reported dilation of blood vessels with lymphocytic and occasional plasma cell perivascular infiltration. However, the clinical manifestations of many of the cases in the epidemic that Grimmer and Joseph¹⁷⁴ studied were quite atypical.

Virus-specific IgM is present at the time of onset of the rash in erythema infectiosum; thus, although the mechanisms of production of the rash (and arthralgia) of erythema infectiosum remain to be elucidated, postulating an immune-mediated pathogenesis is not unreasonable.⁵⁴⁶ The perivascular infiltrations noted by Hoffman²¹² would support this suggestion. However, Schwarz and colleagues⁴³⁸ have found both viral capsid proteins and viral DNA in a skin biopsy specimen of the rash from a patient with erythema infectiosum. They suggest that the rash may be a direct effect of the virus rather than being immune complex mediated.

Intrauterine infection results in infection of the fetus and, frequently, abortion.* The main finding in infected fetuses is hydrops fetalis, which results from the anemia caused by infection of the erythrocyte precursor cells. Intracellular inclusions are seen in nucleated red blood cells; viral particles are identified in the same cells by electron microscopy.⁷⁵ The mechanism responsible for hydrops fetalis stems from severe anemia, and cardiogenic failure results in generalized ascites, edema, pericardial and pleural effusions, and a thick hydropic placenta.¹⁵⁷ Concomitant myocarditis also occurs, which complicates the clinical picture because the blood group P antigen is expressed on fetal cardiac myocytes.^{55,86} The shorter half-life of fetal erythrocytes also exacerbates the disease.⁸⁶

In immunocompromised patients, persistent infection with B19 virus often occurs²⁷⁴ as a result of failure to produce effective neutralizing antibodies.^{86,444} Patients taking immunosuppressive calcineurin inhibitors may be unable to clear B19 virus because these medications inhibit interleukin-2 production and the patients are unable to mount an effective T-helper cell type 1 response.^{86,335}

CLINICAL MANIFESTATIONS

Infection with human parvovirus B19 results in a spectrum of clinical manifestations; classic cases of erythema infectiosum occupy a central position in this spectrum. Other major manifestations include arthritis and arthralgia, intrauterine infection and hydrops fetalis, transient aplastic crisis in patients with a variety of underlying hemolytic illnesses, and persistent infection with chronic anemia in patients with immunodeficiencies. In addition, subclinical, nonexanthematous infection occurs, especially in children.^{13,404}

Other less common illnesses include myocarditis, vasculitis, glomerulonephritis, hepatitis, and neurologic disease. In addition to the established parvovirus B19 disease associations is an ever-expanding list of categories of illness in which evidence of parvovirus B19 infection has been found (Box 152.1).

Erythema Infectiosum

Although a search of the literature related to outbreaks of erythema infectiosum reveals a conspicuous absence of prodromal symptoms in patients, infected volunteers have had febrile episodes with nonspecific symptoms of headache, chills, myalgia, and malaise accompanying the viremic phase of infection with B19 virus (see Fig. 152.1).¹³ These symptoms last for 2 to 3 days and coincide with excretion of virus from the pharynx. This phase is followed by a period of 7 days, during which individuals are free of symptoms before onset of the second, or exanthematous, phase of illness. Most likely, the relatively long period between symptoms in this biphasic illness prevented recognition of the link between these nonspecific prodromal symptoms and erythema infectiosum.

The exanthem in classic cases of erythema infectiosum occurs in three stages.* The first stage begins 18 days after the acquisition of infection and is characterized by a fiery red rash on the cheeks (Fig. 152.2; “slapped-cheek” appearance). The edges of the involved areas may be raised slightly, and a relatively circumoral pallor is present. At

this stage, the appearance may be suggestive of scarlet fever, drug sensitivity or other allergic reactions, or collagen vascular disease. The facial exanthem is aggravated by the transition from outdoors to a warm room.

The second stage of the exanthem occurs 1 to 4 days after the onset of facial involvement and consists of the appearance of an erythematous, maculopapular rash on the trunk and limbs. This rash is discrete initially but spreads to involve large areas. Toward the end of this stage, central clearing of the rash from these areas gives the characteristic lacy or reticular pattern (Fig. 152.3).

The third stage of the exanthem is highly variable in duration (i.e., lasting from 1 to 3 or more weeks) and is characterized by marked changes in the intensity of the rash, with periodic complete evanescence and recrudescence. These fluctuations are related to environmental factors, such as exposure to sunlight and temperature (a hot bath may result in recrudescence in an apparently recovered child).

The rash often is pruritic, especially in adults, and it generally is more prominent on the extensor surfaces; the palms and soles rarely are affected. Slight desquamation has been noted in a small number of patients in most reviews.

Although classic cases of erythema infectiosum are easy to recognize clinically, especially during outbreaks, wide variation in the form of the exanthem can be noted—from a very faint, fleeting rash to a florid exanthem that is confluent over large areas (Fig. 152.4). In many cases, the illness may be indistinguishable from rubella. Yermalovich and colleagues published the experience in Belarus following the institution of a national screening program in 2005 for B19 virus in patients with

FIG. 152.4 Confluent exanthem in a patient with human parvovirus infection.

fever and rash who were measles and rubella negative and reported that more than 35% of patients were B19 positive.⁵³⁹

The overwhelming majority of cases of erythema infectiosum have no exanthem. Kerr and Marsh²⁴⁹ and Condon⁹⁹ noted a few children with pharyngitis.

Other symptoms and signs occur uncommonly in erythema infectiosum (Table 152.1). In general, complaints are expressed more frequently by adults than by children. Headache is reported in approximately a fifth of childhood cases and about half of afflicted adults. Joint pain and swelling and myalgia are particularly troublesome in adults.

Routine laboratory studies are of little use in erythema infectiosum. The leukocyte count usually is normal, although mild eosinophilia is noted occasionally.^{24,48,507,508}

The most common complication of erythema infectiosum is joint involvement; it is relatively rare in children (<10% of cases) but is the norm in adults and occurs in 80% or more of cases.* A range of severity from mild arthralgia to frank arthritis is observed. The joints most commonly involved are the knees, ankles, and proximal interphalangeal joints; symptoms generally are bilateral. The joint involvement usually is transient and lasts only a few days. In some individuals, symptoms may persist for some weeks or, rarely, months. When joint involvement occurs after an exanthem, the diagnosis may be inferred, but such is not invariably the case. As with rubella, the frequency of arthralgia and arthritis is higher in women than in men.⁹⁸

Other Exanthems

Grimmer and Joseph¹⁷⁴ described cases in which the rashes were morbilliform, hemorrhagic, urticarial, vesicular, and resembled erythema multiforme. Their studies were conducted during an epidemic of

erythema infectiosum in Berlin, Germany, in which an estimated 50,000 persons were affected. The cases with markedly unusual manifestations quite possibly were not of the same etiology as the typical cases. Other authors also have noted papular, purpuric, petechial, vesicular, urticarial, and morbilliform eruptions.*

Garcia-Tapia and associates¹⁶⁴ described a 5-year-old girl with erythema multiforme bullosum but without other systemic manifestations. Her serum had B19 virus-specific IgM antibody. Additionally, a papular-purpuric or petechial “glove-and-sock” syndrome has been reported with acute B19 infection.[†] It is more commonly seen in adults but has been noted in children. B19 virus has been identified in the endothelium of cutaneous biopsy specimens from these patients.^{127,427} This unique rash is characterized by petechiae and purpura, with painful or pruritic edema of the hands and feet extending proximally with less severity, and it is self-limited.^{7,188,214,220,325} Henoch-Schönlein syndrome and other vasculitic rashes also have been reported.^{1,88,101,121,202,382,393,434,501}

Grimmer and Joseph¹⁷⁴ stated that most of their patients in the Berlin epidemic had dark red spots on the pharynx, gums, soft palate, and uvula. These cases, again, must be regarded with some suspicion because the investigators also noted genital lesions and conjunctivitis in a few patients.

Aplastic Crisis

In individuals with chronic hemolytic anemia, the profound reticulocytopenia of human parvovirus B19 infection results in depression of hemoglobin concentrations to critical levels.[‡] With resolution of the infection, reticulocytes reappear in the peripheral blood, and hemoglobin concentrations return to the normal steady-state values for these patients. This transient arrest in production of erythrocytes is termed *aplastic crisis* and may occur in any individual whose erythrocytes have a short life span. Examples of such conditions include sickle-cell anemia,^{169,307,442,455,555} hereditary spherocytosis,^{77,140,185,236,373,378,519} thalassemia,^{287,288,412} glucose-6-phosphate dehydrogenase deficiency,¹⁶⁷ and pyruvate kinase deficiency.¹²² However, there are case reports of aplastic anemia secondary to B19 virus developing in immunocompetent patients without underlying diseases.^{178,235,303,330,410,520}

Serjeant and coworkers⁴⁴¹ studied the epidemiology of B19 virus infection over time in 308 children with homozygous sickle-cell disease and in 239 controls with normal hemoglobin. B19 virus infection

*References 9, 15, 16, 24, 192, 197, 355, 414, 417, 509, 522.

accounted for all 91 episodes of aplastic crisis that occurred. Twenty-three additional patients with sickle-cell disease had B19 virus infections; of these, 10 had mild hematologic changes and 13 had no changes. By 15 years of age, approximately 40% of the sickle-cell group and the control group had IgG antibody to B19 virus, thus indicating equal infection rates in the two groups. No patient or control subject had two infections caused by B19 virus.

Smith-Whitley and associates⁴⁵⁵ studied a cohort of 633 patients with sickle-cell disease (including patients with various sickle-cell disease genotypes—SS-, SC-, and Sβ-thalassemia—as well as those receiving chronic transfusions and hydroxyurea) for complications attributable to acute B19 infection. At study entry, 29.8% of the cohort had IgG antibody to B19 virus. The secondary attack rate in the group of children who had siblings with sickle-cell disease was 56%. Thirty-five percent of the total patient population with B19 infection did not have worsening anemia; however, transient red cell aplasia developed in 50% of the children, with those with SC- or Sβ-thalassemia genotypes characterized by less severe disease. Neutropenia developed in 18% of patients and thrombocytopenia in 27%. In only one of seven patients receiving chronic transfusions did transient red cell aplasia develop, potentially because of the lower red cell turnover in these patients.

Rao and colleagues⁴¹¹ found that 70% of patients with transient aplastic crisis admitted to their hospitals during a 7-year period had B19 viral infections. No patients had chronic or recurrent infections. In a study of 48 patients with aplastic crises, Mallouh and Qudah³¹⁰ found 91% to be infected with B19 virus. In addition to the anemia, 21% of the patients had leukopenia, 27% had neutropenia, and 42% had thrombocytopenia. The same investigators noted acute splenic sequestration together with aplastic crisis in three patients with sickle-cell disease and B19 virus infection.³⁰⁹ Lowenthal and associates³⁰¹ noted three young adults with sickle-cell acute chest syndrome associated with B19 virus infection. Yetgin and colleagues⁵⁴¹ reported a case of a 10-year-old child with severe, refractory aplastic anemia ultimately requiring bone marrow transplantation, which resolved the symptoms. Seo and colleagues reported 13 patients, over a 5-year period, with pure red cell aplasia with associated neutropenia diagnosed with B19 virus on bone marrow biopsy.⁴⁴⁰

Interestingly, reports of exanthematous illness occurring after aplastic crisis are rare.^{237,519} However, patients with aplastic crisis require transfusion with packed cells; rashes occurring after such treatment possibly would be regarded as transfusion reactions. Joint symptoms occur fairly frequently in patients with conditions such as sickle-cell anemia; thus, although the symptoms may occur as a result of B19 infection, they may be diagnosed as “painful crises.”

As noted earlier, human parvovirus B19 infection does not result in aplastic crisis invariably in a chronic hemolytic anemic patient. Some individuals escape this complication if they have undergone transfusion recently,¹¹ possibly because of a protective effect of transfused antibody (>60% of donors are immune), the substitution of longer-lived, donated erythrocytes for the patients' own fragile ones, or a combination of these two mechanisms.

In populations in which aplastic crisis does occur, the severity of the episode varies among individuals, perhaps reflecting the variation in erythrocyte life span among these patients.¹¹ In 2013, Gupta and colleagues studied the prevalence of B19 infection in previously healthy, immunocompetent pediatric patients with acquired aplastic anemia.¹⁷⁸

Other Hematologic Manifestations

In addition to pure red blood cell aplasia, numerous other hematologic manifestations, including thrombocytopenic purpura, pancytopenia, hemophagocytic syndrome, neutropenia, and Diamond-Blackfan syndrome, have been observed in association with B19 virus infection.* Thrombocytopenia has been noted as an isolated event; however, idiopathic thrombocytopenic purpura may be associated with aplastic crisis.^{5,150,221,289,352,543} Thrombocytopenia is most commonly related to a decrease in megakaryocytes in bone marrow as a result of the inhibitory effect of the virus on granulocyte-megakaryocyte

colony-forming-units,^{5,405,519} although acquired pure amegakaryocytic thrombocytopenic purpura with resultant absence of bone marrow megakaryocytes secondary to B19 virus also has been described.⁴⁰

Pancytopenia has been observed in association with aplastic crisis, and hemophagocytosis often is demonstrated.* Yufu and coauthors⁵⁴⁸ described a 15-year-old girl with hemophagocytic syndrome and lymphadenopathy resembling histiocytic necrotizing lymphadenitis (Kikuchi disease).

McClain and colleagues³¹⁸ studied 19 children with immune-mediated neutropenia and found by polymerase chain reaction (PCR) assay of bone marrow specimens that 15 had evidence of B19 virus infection.

Arthritis and Arthralgia

As noted earlier, acute arthritis and arthralgia occur commonly in patients with erythema infectiosum. In most instances, the joint symptoms subside within a few weeks, but the arthralgia and arthritis persist occasionally. Researchers also have observed that the joint manifestations caused by B19 virus infection can occur without any exanthem or with an exanthem not typical of erythema infectiosum, and autoantibodies may be produced.^{464,477,500} These findings have led to investigations related to the role of B19 virus in rheumatoid arthritis (RA).†

Nocton and associates³⁶⁸ described the clinical characteristics of 22 children seen in their rheumatology clinic with joint complaints and evidence of recent B19 virus infection. Of this group, 16 were girls and 6 were boys. The youngest patient was 2 years old, and the oldest was 19 years old. Seven of the patients had associated rashes, but none had typical erythema infectiosum. One of these children had a petechial rash on the lower extremities, and another child had a past history of urticaria. Fever, anorexia, malaise, or fatigue occurred in 11 of the patients.

Of the 22 patients, 20 had arthritis and 2 had only arthralgia. The knee joints were most commonly involved. The following frequency of specific joint involvement was reported: knees, 82%; ankles and wrist, 41%; elbows, 32%; neck, small joints of the hands and feet, and hips, 27%; shoulders, 23%; and sternoclavicular joints, 9%. Ten of the patients had involvement of five or more joints, and in 12 patients the pattern was pauciarticular, with four or fewer joints involved. Two patients had only a single joint involved, and two patients had migratory illness.

The duration of the arthritis or arthralgia was less than 6 weeks in 50% of the children and less than 4 months in 64%. Of the 11 children with illness lasting longer than 2 months, 6 had manifestations that fulfilled the criteria for the diagnosis of juvenile rheumatoid arthritis (JRA). Selected laboratory results were as follows: the erythrocyte sedimentation rate was greater than 25 mm/h in 32% of the children, antinuclear antibody titers were greater than 1:40 in 7 of 21 of the patients, and 3 of 6 children had a low total hemolytic complement (CH₅₀) value.

The relationship between B19 virus infection and JRA, RA, and adult Still disease has been studied extensively during the past 15 years, but the findings are difficult to interpret.‡ Clearly, B19 virus can cause illnesses that fulfill the criteria for a diagnosis of JRA^{60,368,377,522} and adult Still disease.^{239,298} However, three possible scenarios need to be considered: (1) B19 virus causes a similar illness, (2) B19 virus infection triggers the onset of an illness caused by another condition, and (3) B19 virus directly causes JRA, adult Still disease, and RA.

In one study involving patients with refractory RA and refractory polyarticular JRA, researchers found that both groups had a significantly higher frequency of IgG B19 virus antibody as determined by enzyme-linked immunosorbent assay (ELISA) than did aged-matched controls.³²⁸ However, when the data in this study were examined, the prevalence of antibody in the control population clearly was less than expected. In another study, Kishore and colleagues²⁵⁴ studied IgM antibody to B19 virus by ELISA and found that 28% of patients with JRA, 8% of controls, and none of the patients with RA had positive values. They

†References 73, 98, 152, 182, 197, 210, 238, 239, 254, 328, 334, 364, 368, 407, 458, 464, 477.

‡References 42, 60, 64, 109, 197, 238, 290, 291, 298, 304, 326, 328, 347, 348, 355, 368, 377, 396, 407, 458, 477, 494, 522.

*References 5, 47, 143, 150, 185, 194, 195, 197, 221, 239, 268, 286, 289, 292, 318, 346, 352, 408, 480, 490, 495, 515, 543.

interpreted their JRA findings to be either triggering B19 virus infections or perhaps concurrent infections in patients with established JRA. In a provocative study, Takahashi and coworkers⁴⁷⁷ found B19 virus DNA in the synovial tissue of 30 of 39 patients with RA. The data suggested that the virus identified in synovial tissue was active and led to their conclusion that B19 virus is involved in the initiation and perpetuation of RA synovitis. In contrast, Nikkari and associates^{364,366} in Finland performed extensive studies and noted that chronic rheumatoid-like arthropathies triggered by B19 virus occasionally occur. However, their data do not support a general role for B19 virus in the etiology or pathogenesis of RA. Varache and colleagues investigated the utility of routine viral screening in patients with early RA and determined that the seroprevalence of B19 was not increased compared with the general population.⁵⁰⁰ B19 infection can lead to increased circulation of immune complexes, endothelial injury, inflammation, and exacerbation of underlying vasculitic disease.⁶³

Tyndall and colleagues⁴⁹² described an adult woman with erosive polyarthritis associated with B19 virus infection, and Samii and coworkers⁴²⁶ reported two adults with bilateral carpal tunnel syndrome associated with B19 virus infection. Berg and colleagues³⁶ could find no association with either IgG or IgM antibody to B19 virus and fibromyalgia in a study of 26 adult women and matched controls. Guillaume and colleagues¹⁷⁶ reported a case of chronic arthropathy in the lumbar facet joints after B19 infection.

Other rheumatic and vasculitic syndromes have been noted in association with parvovirus B19 infection; however, the strength of these associations is unclear. These associated syndromes include fibromyalgia,³⁵⁸ systemic lupus erythematosus,^{102,114,207,218,445} Kawasaki disease, leukocytoclastic vasculitis, polyarteritis nodosa, Wegener granulomatosis,¹²⁶ chronic fatigue syndrome,^{243,244,319} systemic sclerosis,^{146,381,380} giant-cell arteritis, transient anticardiolipin syndrome and transient antiphospholipid syndrome,¹⁹ hemophagocytic syndrome,^{47,460} mixed cryoglobulinemia,⁸⁵ Henoch-Schönlein purpura,^{88,202,382} uveitis with and without associated systemic disease,²⁰³ myofasciitis,²¹⁷ and Raynaud phenomenon.*

Infection in Immunocompromised Patients

Immunocompromised patients may suffer chronic B19 virus infections.[†] These patients have persistent anemia caused by continuous lysis of red cell precursors. Lackner and colleagues reviewed 1059 consecutive patients with various hematologic and oncologic diseases and characterized 35 patients diagnosed with B19 infection.²⁷⁸ B19 infection has been commonly seen in children with acute lymphocytic leukemia.[‡]

Other immune deficiency states in which chronic B19 virus was documented include Nezelof syndrome, acute myeloid leukemia, chronic myeloid leukemia, Burkitt lymphoma, lymphoblastic lymphoma, myelodysplastic syndrome, astrocytoma, Wilms tumor, HIV infection,^{90,356} severe combined immunodeficiency, bone marrow transplantation,^{193,250,402,468} other organ transplants,^{34,76,128,272,335,385} systemic lupus erythematosus,⁴⁷⁰ and patients receiving chemotherapy.^{126,144,201,273} The immune deficiency in the aforementioned conditions can be a primary event or a secondary event related to treatment.

Eid and colleagues¹²⁹ reviewed 98 transplant recipients in whom acute parvovirus B19 infection developed after transplantation. The median time to B19 disease was 7 weeks after transplantation. Anemia developed in 99%, leukopenia in 38%, thrombocytopenia in 21%, and allograft loss or dysfunction in 10%. Three patients died of myocarditis and cardiogenic shock as a result of B19 infection. B19 virus was associated with chronic renal allograft injury.³²

Patients with chronic anemia have high persistent concentrations of B19 virus in their serum, although the values (10^8 particles/mL) are less than those seen in primary infections (10^{10} – 10^{11} particles/mL) in healthy individuals and in patients with hemoglobinopathies.

Viremia and anemia may, if untreated, persist for years. Fatigue and pallor are the most common clinical symptoms; other findings of B19

virus infection, such as exanthem and arthralgia, occur rarely. Because of immunodeficiency, IgM antibody studies generally are not useful in making the diagnosis. Therefore, the diagnosis of persistent B19 virus infection depends on demonstration of specific B19 antigen or DNA in blood.⁶³

In immunocompromised patients, persistent infection with B19 virus often occurs as a result of failure to produce effective neutralizing antibodies.^{63,86,268} Intravenous immunoglobulin (IVIG) preparations have been used successfully for the treatment of B19 virus in immunocompromised patients.* Patients taking immunosuppressive agents, especially calcineurin inhibitors, may be unable to clear B19 virus because these medications inhibit interleukin-2 production, and the patients are unable to mount an effective T-helper cell type 1 response.^{86,335} It may be necessary to reduce the dose of immunosuppressive agents in addition to IVIG treatment to successfully eradicate B19 virus.^{31,130,295} LaMonte and associates²⁷⁹ reported five children (three HIV-infected children and two otherwise normal children) with chronic infections without B19-associated anemia.

Intrauterine Infection

Although a large epidemiologic study of an outbreak of erythema infectiosum over 40 years ago failed to reveal evidence of teratogenicity, virologic and serologic studies conducted during the past 25 years indicate that B19 virus crosses the placenta and causes infection in the fetus.[‡] Infection in pregnancy results in fetal hydrops because of severe anemia and leads to cardiac failure, fetal death, and miscarriage.^{86,115,314,375}

Bonvicini and colleagues followed 72 pregnancies complicated by B19 infection. Vertical transmission was documented in 39% of the pregnancies, B19 fetal hydrops in 11.9%, and overall fetal demise in 10.2%, with the highest rate of congenital infection and fatal outcome with maternal infection prior to 20 weeks of gestation.⁴⁵

To determine the rate and outcome of fetal involvement after infection in pregnant women, two prospective studies were performed in England during a 3.5-year period from January 1985 to June 1988⁴⁰⁹ and from 1992 to 1995.³²⁷ These two studies included 427 pregnant women infected with B19 virus; 367 infants survived, and 129 of them had follow-up examinations at 7 to 10 years of age.³²⁷ The excess rate of fetal loss was 9%; such loss occurred only during the first 20 weeks of gestation. Seven cases of fetal hydrops occurred. Three of these fetuses survived; two of the three received intrauterine transfusions. None of the surviving infants in the two studies had abnormalities attributable to B19 virus infection, and no later effects were found at 7 to 10 years of age. Of the infants exposed in utero after 20 weeks of gestation, more than half were infected, but no clinical effects were identified. In a study by Nyman and colleagues,³⁷⁶ the frequency of first-trimester fetal loss associated with B19 virus was 3%, with 12% occurring in the second trimester. Maternal B19 seroconversion during pregnancy was not associated with lower birth weight or reduced length of gestation in live-born children in a study of 35,940 pregnant women in Norway.⁴²⁸

In a study in Connecticut related to a large outbreak of erythema infectiosum in which 39 infected pregnant women were monitored, two miscarriages occurred.⁴¹⁹ The frequency of fetal loss caused by B19 virus infection was estimated to be 5%. In another study in Spain, fetal loss occurred in only 1 of 60 women infected with B19 virus during pregnancy.¹⁷² Enders and colleagues¹³⁶ studied 1018 pregnant women with acute parvovirus infection. The overall rate of fetal loss was 6.3%, with a rate of 11% if the B19 infection occurred in the first 20 weeks of gestation. The overall rate of hydrops fetalis was 3.9%; the peak incidence occurred between 17 and 24 weeks of gestation.

De Jong and colleagues¹¹¹ investigated the neurodevelopmental impairment in children treated with intrauterine transfusion for fetal anemia due to B19 infection. Twenty-eight children were evaluated at a median age of 5 years, and the study showed increased impairment when compared with the general population.

Koch and colleagues²⁵⁹ performed follow-up examinations on 19 infants born to mothers who had serologically confirmed B19 virus infection between the 4th and 38th weeks of gestation. In none of these infants did hydrops develop during pregnancy, and all were normal after birth. One child whose mother had erythema infectiosum at approximately the 20th week of gestation had a persistent asymptomatic infection for at least the first 7 months of life. Donders and coworkers¹¹⁸ noted a child in whom a sonogram demonstrated fetal hydrops at 30 weeks of gestation. Cordocentesis revealed a hemoglobin concentration of 2.4 g/dL. One week later, a hydropic 1550-g infant was delivered by cesarean section. The neonate's bone marrow showed an arrest in erythropoiesis with giant pronormoblasts. The infant received multiple transfusions for the first 4 months of life, and B19 viral DNA was identified in the infant's blood at 19 weeks of age. At 2 years of age, this child was found to be clinically, hematologically, and immunologically normal. In contrast to the case just noted, Brown and associates⁵⁶ reported an infant with a similar exposure and delivery history who had persistent anemia and, despite therapy, was dependent on transfusions at 4 years of age. In addition, Brown and associates⁵⁶ reported two other infants who had received intrauterine transfusions for fetal hydrops and had persistent anemia after birth.

Candotti and colleagues⁶⁵ studied plasma samples from 885 pregnant women from Ghana and found that, contrary to the high rate of B19 transmission during primary viremia in pregnancy, pregnant women with B19-specific IgG and low levels of B19 DNA by PCR did not transmit virus to the fetus. Weiffenbach and colleagues⁵¹⁶ determined B19 viral DNA and anti-B19 viral antibody titers in maternal and fetal blood samples obtained from 41 pregnancies complicated by prenatal B19 viral infection and determined that anemia or hydrops due to B19 virus is most likely due to a limited maternofetal transfer of IgG and a poor fetal antibody response.

At the present time, a large number of infants who were exposed to the B19 virus in utero have been studied, with no convincing evidence of specific congenital malformations.^{252,341,409,418,419,528} However, van Elsacker-Niele and associates⁴⁹⁹ noted B19 virus infection in cells other than those of the erythroid series in two aborted fetuses. Ocular malformation was found in one, and evidence of extensive inflammatory reactions in all fetal and placental tissues was noted in both. Fishman and associates report a case of fetal cardiomyopathy with atrioventricular nodal disease.¹⁴⁸ Carlsen and colleagues suggest a higher mortality rate in B19-infected fetuses with fetal trisomy.⁶⁶

Tiessen and colleagues⁴⁸³ reported an aborted fetus with a bilateral cleft lip, alveolus, and palate; micrognathia; and webbed joints. In another aborted fetus, ocular abnormalities similar to those seen in congenital rubella were observed.⁵¹⁸ In a neonate with anemia, blueberry muffin rash, and hepatomegaly, parvovirus B19 viral gene sequences were found in the liver and placenta.⁴⁵¹ Gulen and associates¹⁷⁷ described a premature infant born at 29 weeks of gestation with leukoerythroblastosis associated with B19-specific IgM and IgG antibody in both the mother and infant.

Yeh and colleagues⁵³⁸ described severe, transient dyserythropoietic anemia in a puerperal woman with preeclampsia and eclampsia with concomitant B19 infection.

Neurologic Illness

Parvovirus B19 has been linked with various clinical syndromes, including neurologic manifestations.²⁹ Douvovianis and colleagues¹¹⁹ reviewed the literature of 81 cases of neurologic disease associated with B19 virus from 1966 to 2008. The median patient age was 9 years, the majority were immunocompetent patients, and there were no differences in the prevalence of sequelae noted between immunocompetent patients and patients with altered immunity. There were also no differences in sequelae between patients with central nervous system manifestations who received intravenous immunoglobulin with or without corticosteroids and those patients with central nervous system manifestations who did not.

Two children with encephalitis in association with erythema infectiosum were noted in the era before discovery of the causative role of B19 virus in erythema infectiosum.^{26,51} In the present era, a number of

cases of aseptic meningitis and encephalitis have been reported in association with B19 virus infection in both children and adults.* These cases have been documented by the demonstration of specific B19 virus IgM antibody or the presence of B19 viral DNA in cerebrospinal fluid. Bilge and colleagues⁴¹ reported a 12-year-old boy with a history of renal transplantation who had recurrent episodes of encephalopathy and focal neurologic defects associated with B19 DNA in blood and bone marrow and on skin biopsy specimens. He was treated successfully with IVIG. Nolan and colleagues³⁶⁹ reported an HIV-positive patient in whom parvovirus B19 encephalitis developed during immune reconstitution while receiving highly active antiretroviral therapy. Chorea-encephalopathy, with parvovirus B19 DNA in both serum and cerebrospinal fluid, developed in a previously healthy 8-year-old girl.¹⁴⁹

Other neurologic illnesses associated with B19 virus infection²⁸ include postinfectious neuralgic amyotrophy,³⁹⁴ Guillain-Barré syndrome,^{329,481} parainfectious myelitis,⁴³¹ acute bilateral carpal tunnel syndrome,^{302,426} mononeuritis multiplex,^{4,293} stroke,^{175,311} transverse myelitis,⁴⁷² cerebellitis,⁴⁹³ and numbness and tingling of the fingers.¹⁴³

Myocarditis

Myocarditis in association with parvovirus B19 infection has been observed in immunocompetent children and adults.* B19-associated myocarditis can progress to chronic dilated cardiomyopathy.^{227,270,271,280,299,387,388,552} In a study of 3345 patients who underwent cardiac biopsy for suspected myocarditis or dilated cardiomyopathy, Pankuweit and colleagues³⁸⁸ found B19 DNA by PCR in 17.6% of patients with dilated cardiomyopathy without significant inflammation, and inflammatory heart disease, ventricular dilation, and reduced ejection fraction were noted in 33.3% of patients. In 2012, Molina and colleagues³³² published a retrospective study characterizing the outcomes of 19 children with B19 myocarditis. They noted a varied presentation from subclinical illness, subacute congestive heart failure to fulminant myocardial involvement. Kühl and associates²⁷¹ showed that viral persistence in the setting of myocarditis or dilated cardiomyopathy was associated with progressive deterioration of the left ventricular ejection fraction whereas elimination of virus resulted in significant improvement in left ventricular function.

In a study by Wang and colleagues,⁵¹¹ B19 virus was detected by nested PCR in cardiac tissues in 7 of 42 patients with congenital heart disease and in none of the 38 controls, thus suggesting a correlation between B19 virus and congenital heart disease.

Enders and associates¹³⁴ described two children with life-threatening myocarditis. One of these children died, and the second received a cardiac transplant. The illnesses in both these children occurred in the spring; one had joint pain and urticarial lesions on the flexor surfaces of both arms, erythematous macules on the abdomen and upper part of the chest, and purpuric lesions on the back. Both children had B19 viral DNA identified in the heart and B19-specific IgM antibody.

Nigro and colleagues³⁶¹ noted three young children—aged 7, 12, and 18 months—with acute lymphocytic myocarditis and parvovirus B19 infection. Two of these children exhibited full cardiac recovery, but chronic persistent myocarditis developed in the other child. Papadogiannakis and coworkers³⁸⁹ reported a healthy 11-month-old child who had severe respiratory distress and died of sudden cardiac arrest within 3 hours of admission because of parvovirus-associated lymphocytic myocarditis. Zack and associates⁵⁵⁰ reported a 5-year-old girl who suddenly collapsed and died of acute myocarditis secondary to parvovirus B19 infection. Significant lymphocytic infiltration of the sinoatrial node and perivascular infiltration around the atrioventricular node probably resulted in conduction disturbances and death. Jonetzko and colleagues²³² reported a case of fatal parvovirus B19-associated myocarditis in a liver transplant recipient. Parvovirus B19 infection also can mimic acute myocardial infarction^{62,270} and isolated diastolic dysfunction in adults.⁴⁸⁸

It is hypothesized that the blood group P antigen on the endothelial cells of coronary vessels is a portal for infection and that such infection results in endothelial dysfunction, impairment of the coronary microcirculation, and inflammation of the myocardium.^{28,270,280,532} The blood

*References 28, 41, 72, 149, 187, 197, 199, 238, 248, 264, 369, 383, 465, 471, 474, 514, 536.

*References 33, 44, 62, 113, 116, 134, 265, 270, 280, 299, 332, 349, 361, 387–389, 395, 423.

group P antigen is not present on the myocytes of children and adults; however, it is present on fetal myocytes.^{55,268,270,280}

Acute Hepatitis

Acute hepatitis has been noted as a manifestation of B19 virus infection.^{189,266,459,542} Yoto and coworkers⁵⁴² described seven children with acute hepatitis in association with B19 virus infection. They carefully studied and ruled out other common causes of acute hepatitis. Sokal and associates⁴⁵⁹ reported fulminant hepatitis in four children younger than 5 years of age in association with parvovirus B19 infection. Their patients had a distinct clinical pattern consisting of low serum bilirubin concentrations and rapid recovery of liver function without transplantation. Nobili and colleagues⁴⁶⁷ reported a case of autoimmune hepatitis followed by severe autoimmune hemolytic anemia in a 1-month-old boy with parvovirus B19 infection. Treatment with cyclosporine and prednisone resulted in resolution of his symptoms.

Hsu and associates²¹⁵ studied 54 patients with B19 virus infection in addition to hepatitis B virus (HBV) infection and 51 patients with hepatitis C virus (HCV) infection who were not taking immunosuppressive drugs. The study found that the prevalence of parvovirus B19 DNA was high in patients with HBV (85.2%) or HCV (70.6%). Coinfection with B19 and HBV or HCV did not increase the frequency of liver dysfunction in these patients with chronic hepatitis.^{215,285} Additionally, in a study by Wong and associates,⁵³⁰ there was no significant difference in the prevalence of parvovirus B19 DNA in liver biopsy specimens from patients with fulminant hepatitis or hepatitis-associated aplastic anemia and those with HBV or HCV infection. However, Dwivedi and colleagues showed that pediatric patients with fulminant hepatic failure who had high prevalence of B19 associated with coinfection of other hepatitis viruses had relatively severe disease and poor outcome.¹²⁴

Other Illnesses

One adult patient had chronic red cell aplasia for a 10-year period that was treated with regular blood transfusions.²⁷⁶ After a diagnosis of persistent B19 virus infection, the patient was treated with IVIG, which resulted in an apparent cure. A presumably immunologically normal woman had recurrent episodes of paresthesia over the course of a 4-year period in conjunction with persistent B19 viral DNA in her blood.¹⁴² Evidence of persistent infection in immunologically normal patients has been noted in other studies.^{246,350}

Kerr and associates²⁴⁷ studied 53 patients who had contracted acute B19 virus illnesses. Seven of those studied had B19 viral DNA demonstrated in serum specimens 26 to 65 months after their acute illnesses. All seven were women, and four were asymptomatic. Of the other three, one had chronic hemolytic anemia, one had persistent arthralgia of the knees, and the last had arthralgia and chronic fatigue syndrome.

Multiple case reports have described patients with chronic fatigue syndrome and persistent parvovirus B19 DNA in their serum.^{226,243,244,315,319} In 2002, Kerr and colleagues²⁴³ described three patients with chronic fatigue syndrome and chronic B19 virus infection treated with IVIG. Such treatment resulted in the clearance of B19 viremia, improvement of symptoms, and resolution of cytokine dysregulation.

Faden and associates¹⁴² described a nurse with recurrent episodes of paresthesia who had B19 viral DNA demonstrated in her serum for almost a 4-year period. This woman also had persistent serum IgM antibody to B19 virus.

Lymphadenitis associated with parvovirus B19 infection has been described by many authors. Tsuda and coworkers⁴⁸⁹ reported five young adults with cervical lymphadenopathy associated with B19 virus infection. All had fever, one had arthralgia, and all had leukopenia. Morinet and colleagues³³⁸ described a 27-year-old man with pseudoappendicitis or acute mesenteric lymphadenitis and serologic evidence of B19 virus infection. A 16-month-old boy had peripheral facial palsy, parotitis, and intraparotid lymphadenitis with evidence of parvovirus B19 IgM antibody and IgG antibody seroconversion.³¹³ Johnson and associates²³⁰ described an 18-year-old woman with parvovirus B19 resulting in necrotizing lymphadenitis, and Knösel and colleagues²⁵⁵ reported unilateral cervical lymphadenopathy in a 16-year-old girl. In both cases, parvovirus B19 DNA was detected by PCR on lymph node biopsy specimens.

Parvovirus B19 infection also has been shown to induce proliferative glomerulonephritis, usually endocapillary or mesangioproliferative (or both), with hypocomplementemia and spontaneous recovery.^{219,225,337,379,478,479,513} Ieiri and colleagues²¹⁹ studied 10 patients with acute glomerulonephritis associated with human parvovirus B19 infection. These authors found that this specific renal disease characterized by endocapillary hypercellularity was associated with hypocomplementemia, leukopenia, positive antinuclear antibody, and a female preponderance (9 of 10 patients). Ohtomo and associates³⁷⁹ reported a healthy 8-year-old boy with erythema infectiosum and glomerulonephritis with immune complex deposits associated with B19 virus diagnosed by both monoclonal antibody against human parvovirus B19 antigen and nested PCR on renal biopsy. The association between parvovirus B19 and sepsis also has been reported by multiple authors. These patients exhibited shock, severe respiratory distress, and parvovirus B19 infection.^{23,145,339,389,512} Parvovirus B19 infection has also been linked to generalized edema in 2 previously healthy women.^{503,524}

DIFFERENTIAL DIAGNOSIS

Because the exanthem of erythema infectiosum is unique, its diagnosis should be easy. During epidemics, no difficulties should arise, but sporadic cases can be a problem. In the differential diagnosis, rubella and scarlet fever are of most concern. Because rubella virus has been recovered from some patients with illness thought to be erythema infectiosum²⁶ and because an erythema infectiosum-like illness was observed in volunteers who underwent intranasal administration of a rubella virus strain recovered from a patient with erythema infectiosum-like illness,⁴³² this diagnostic possibility always should be considered. When the risk for development of congenital rubella is a possibility, rubella-specific diagnostic tests should be performed (see Chapter 174).

Erythema infectiosum can be differentiated from scarlet fever by the usual lack of pharyngitis in the former and a positive culture for *Streptococcus pyogenes* in the latter. Other differential diagnostic considerations are other infectious exanthems (see Chapter 58), collagen vascular diseases, drug reactions, and allergic responses to environmental substances.

Although a presumptive diagnosis of B19 virus infection may be made by exclusion of other etiologic possibilities, a definitive diagnosis can be made only by specific serologic tests or identification of B19 antigens or DNA in blood or tissue specimens.

Aplastic crisis in a patient with chronic hemolytic anemia can be diagnosed by finding a hemoglobin concentration that is 2 g/dL or more below the steady-state value for that patient, together with a reticulocyte count either less than 0.2% of the steady-state value or elevated above the steady-state value (indicative of hyperplasia of erythrocyte precursors in the recovery phase). Although B19 virus infection is the most common cause of aplastic crisis, moderate to severe degrees of hypoplasia may be associated with systemic bacterial infections (e.g., *Salmonella*, *Streptococcus pneumoniae*) or marrow-suppressive drugs.^{323,442}

DIAGNOSIS

Several tests have been developed and refined that allow a reliable serologic diagnosis of acute and past B19 virus infection to be established and B19 virus in blood and tissues to be demonstrated.* IgM and IgG antibody can be detected by enzyme immunoassay, hemadherence, radioimmunoassay, or immunofluorescence; antigen can be detected by DNA hybridization, PCR, or electron microscopy.

In a normal host, acute or recent infection is determined best by demonstration of specific IgM antibody. In immunocompromised patients with suspected acute or chronic infection, the diagnosis is made by detection of antigen in blood. Similarly, detection of antigen also can be performed early in aplastic crisis and to study aborted fetal tissues. Gallinella and colleagues¹⁶³ recommend both specific IgM and B19 DNA PCR to establish a diagnosis of B19 infection. Past infection

*References 9, 14, 21, 35, 59, 61, 67, 71, 74, 92, 94, 95, 107, 108, 137, 157, 163, 208, 211, 251, 258, 262, 324, 336, 359, 424, 435, 437, 475, 510, 529, 553.

and immunity to B19 virus are determined by demonstration of specific serum IgG antibody.

Some caution should be observed in accepting the results of IgM serology and antigen detection in unusual clinical circumstances.⁵³ The sensitivity and specificity of the various serologic tests vary, and additional false-positive and false-negative results can be expected, depending on the skill of workers in individual laboratories.^{61,94,486,496} Antigen-detection systems can be contaminated, and such contamination may not be discernible by conventional controls. When the results of tests on specimens from patients with unusual illnesses are positive, repeating the tests in a different laboratory is worthwhile.

Söderlund and associates⁴⁵⁷ reported an IgG avidity assay that is highly sensitive and specific for the identification of recent primary infection with parvovirus B19. Enders and coworkers¹³⁵ also recommended VP1 IgG avidity or VP2 epitope-type specificity assays in the presence of low-level IgM or B19 DNA to confirm or refute the diagnosis of B19 infection during pregnancy. Because there is a window of 7 days after initial infection occurs until the development of IgM-specific B19 antibody and because IgM can be negative or low in the presence of overt hydrops fetalis, both serology and B19 DNA PCR are recommended on both maternal and fetal sera (or cord blood).¹²⁸

Beersma and colleagues³⁵ demonstrated the superiority of B19 VP2 IgM ELISA by showing high correlation with elevated levels of B19 DNA in sera. Persistent infection may be determined by the presence of IgG antibody to NS1.⁵⁰⁵

If parvovirus B19 infection is suspected in pregnancy, ultrasound should be performed to assess for fetal anemia and hydrops (excess of fluid in at least two body compartments of the fetus).¹²⁸ The use of middle cerebral artery peak systolic velocity for the detection of fetal anemia may be a useful adjunct to ultrasound scanning.^{103,343}

TREATMENT AND PROGNOSIS

No specific treatment of B19 virus infection exists. Symptomatic therapy for erythema infectiosum rarely is necessary, especially in children. Starch baths may be helpful in reducing pruritus. Arthralgia or arthritis may be troublesome and may be treated with analgesics.

The outlook in virtually all cases of erythema infectiosum is excellent. If patients with aplastic crisis receive transfusions with packed erythrocytes when necessary, the prognosis for these patients also is excellent. If B19 virus infection occurs during pregnancy, the pregnancy should be monitored carefully. At delivery, examination of cord blood or blood from the neonate for detection of virus and IgM antibody will reveal whether the virus has crossed the placenta and infected the neonate. When infection has occurred, the child should be examined carefully for any defect and monitored for some years to exclude the possibility of delayed sequelae.

Some researchers have suggested that pregnant women with symptomatic B19 virus infection be observed for fetal aplastic crisis by monitoring maternal serum for elevated levels of α -fetoprotein.⁶⁸ If levels are found to be elevated, serial ultrasonography can be performed to detect hydrops fetalis. Fetal hydrops can be treated by in utero transfusions^{139,171,422}; however, there is a risk for infection and the potential for congenital malformations with cordocentesis and fetal transfusion. Enders and colleagues¹³⁶ reported that 84.6% of those with severe hydrops fetalis survived to delivery. In 2005, Matsuda and colleagues³¹⁶ successfully treated a B19-infected fetus with hydrops at 21 weeks of gestation with two injections of B19 IgG-rich immunoglobulin injected into the fetal peritoneal cavity. The fetal ascites and pericardial effusion resolved completely 8 days after the initial injection, and a healthy infant was born at 38 weeks of gestation without evidence of cardiac dysfunction or B19 DNA detected in serum. Therapeutic abortion is not indicated for pregnant women with documented B19 virus infection.

Patients with chronic myocarditis caused by B19 virus and acute heart failure caused by B19 have been treated successfully with IVIG.^{6,466} Chronic myocarditis secondary to B19 also has been treated with immunosuppressive agents, including corticosteroids and cyclosporine.^{280,349,423} Ito and associates²²⁴ described a patient with baseline refractory autoimmune hemolytic anemia who was taking immunosuppressive medications while infected with B19 virus. The patient had a

complicated course of illness; persistent pure red cell aplasia subsequently developed but resolved after treatment with cyclosporine and IVIG.

Immunocompromised patients with chronic B19 virus infection can be treated successfully with IVIG preparations,^{42,60,117,197,203,223,238,261,446} as can other patients without demonstrated immune deficiencies who have chronic infections.^{142,224,226,345,466} Although the amount of specific B19 virus antibody varies among different IVIG products, all contain significant concentrations.¹¹⁷ No formal treatment studies have been performed, and several different treatment programs have been used. Even though some cures have been achieved with single-dose IVIG therapy, we favor an initial 4-day course with 500 mg/kg per day. After the patient has received treatment, the viremia should cease and clinical improvement should occur. Some immunocompromised patients have required repeated treatment courses.

PREVENTION

B19 virus is spread by the oral and respiratory routes, and virus shedding during routine infection occurs when patients are not aware of their illness. Because B19 virus infections occur in outbreaks, the virus can be widespread in a community, with many infections going unrecognized.

Patients with erythema infectiosum do not need to be isolated because they have passed their period of infectivity. Although patients with aplastic crisis also usually are past the period of virus shedding, they should be isolated because some will be shedding virus at the time of initial evaluation. All patients with chronic infection should be considered contagious until treated with IVIG and demonstrated to be nonviremic.

Pregnant women are of particular concern during an outbreak.^{70,166} The rate of parvovirus seropositivity is approximately 50% in women of childbearing age; thus, no risk exists in approximately half of those who might become exposed. Determining an IgG antibody titer can allay the fear in those who are antibody positive. Cartter and associates⁷⁰ examined occupational risk factors for B19 virus infection in pregnant women. They found the following rates of infection: school teachers, 16%; daycare workers, 9%; homemakers, 9%; and women working outside the home, 4%. In another study, Gillespie and colleagues¹⁶⁶ found that the greatest risk for infection occurred in school and daycare personnel. These results suggest that in certain circumstances (in older women and those with past fertility problems), having women in high-risk occupations avoid the workplace during the outbreak period might be reasonable.

Technological advances have led to the development of experimental recombinant vaccines that show considerable promise for effective prevention.^{27,97,139,155,194,546} These vaccines could be useful in selected populations, such as patients with hemoglobinopathies and seronegative women of childbearing age.

Human Bocaviruses

153

Jennifer E. Schuster • John V. Williams

Human bocavirus (HBoV) was discovered in 2005 by Allander and colleagues.³ Studies have shown that HBoV infection is ubiquitous worldwide and that nearly all adults are seropositive. HBoV has been detected in respiratory specimens from persons with acute respiratory illness and in stool specimens from patients with gastroenteritis. However, controlled studies do not always show a consistent association between HBoV and acute respiratory disease, and prolonged shedding of HBoV further clouds the issue of causality. Much remains to be elucidated about the biology and epidemiology of this virus.

HISTORY

Allander and colleagues discovered HBoV using a novel molecular virus discovery approach on nasopharyngeal aspirates collected from patients with acute respiratory illness.³ The method consisted of pooling clinical specimens, concentrating virus particles by ultracentrifugation, depleting human DNA, amplifying viral DNA by random polymerase chain reaction (PCR), sequencing the PCR products, and aligning the sequences to published databases. The group tested nasopharyngeal aspirates collected from patients with acute respiratory illness. Novel parvovirus-like sequences were identified that most closely aligned with bovine parvovirus (BPV)²⁶ and minute virus of canines (MVC)¹¹; thus, the new virus was designated HBoV. Related bocaviruses have been discovered in pigs,¹³ gorillas,⁷⁹ and sea lions.⁹⁷

PROPERTIES

HBoV is a member of the *Parvoviridae* family, subfamily *Parvovirinae*, genus *Bocaparvovirus*. Like other parvoviruses, HBoV is a small, nonenveloped virus with a single-stranded, linear DNA genome of ~5 kb. The capsid size is ~22 to 28 nm.⁶¹ The genomic organization of HBoV closely resembles that of the other known bocaviruses BPV and MVC. Like all members of the *Parvovirinae* subfamily, there are two major open reading frames (ORFs) encoding a nonstructural protein (NS1) and two capsid proteins (VP1 and VP2), respectively. However, like BPV and MVC, HBoV also has a third ORF. In BPV and MVC, this ORF encodes a nonstructural protein with unknown function, NP1.^{26,139} HBoV has ~42% amino acid identity of both major ORFs to BPV and MVC and thus represents a distinct virus. Other HBoV genotypes have been identified and tentatively designated species HBoV2, HBoV3, and HBoV4.^{8,80,81} Some of these may have arisen from recombination events among different HBoV species.^{53,80,84} Nucleotide identity among these different HBoVs ranges from 73% to 88%.^{29,80} There is evidence of some antigenic cross-reactivity among

these viruses,⁷⁶ and the biological significance of the different types is not clear.

HBoV has been cultivated in well-differentiated primary airway epithelial cell cultures.^{41–43} No cytopathic effects were observed, but increasing amounts of HBoV DNA and RNA in cell cultures suggested active viral replication. In one study, HBoV-infected cells exhibited loss of cilia, disruption of tight junctions, and loss of transepithelial resistance.⁴² Moreover, supernatant from infected cells could successfully pass infection to a new cell monolayer, confirming production of infectious viral particles.

HBoV exhibits a complex transcriptional strategy, with multiple monocistronic, polycistronic, and variably spliced mRNAs.^{25,43} The overall transcription profile of HBoV is similar to that of BPV and MVC.^{128,145} The cellular site of HBoV replication is not known, though viral proteins NS1 and NP1 localize to the nucleus.^{25,98} NP1 interferes with innate immune responses by blocking interferon beta production via interferon regulatory factor 3 signaling, is required for mRNA splicing and expression of viral capsid proteins, and induces apoptosis in host cells.^{144,155,158} VP2 modulates interferon beta signaling.¹⁰⁵ No animal model of infection has been identified. However, a reverse genetics system has been established for HBoV, which will enhance study of the biology and pathogenesis of this virus.⁶⁶

EPIDEMIOLOGY

HBoV infections have been identified in humans worldwide. Following the discovery of the virus in pooled respiratory specimens, a number of groups tested convenience sample sets collected from patients with acute respiratory illness. HBoV was detected by PCR in these specimens at rates between 5% and 20%.^{5,9,51,52,83,92,106–108,142} The virus is detected most frequently in children less than 2 years old. Australian investigators detected HBoV in 18 (6%) of 324 specimens collected during autumn and winter in a single season from children with acute respiratory illness.¹⁴¹ HBoV was present in 18/318 (6%) Japanese children with lower respiratory infection.¹⁰⁶ Investigators in Connecticut tested 425 hospital laboratory specimens collected from children younger than 2 years and detected HBoV in 22 (5%), all between October and April.⁸³ HBoV was detected in hospitalized children with acute respiratory illness in Vietnam (78/1082 [7%]),¹⁴⁷ Thailand (39/304 [13%]),⁶⁴ and China (386/3022 [13%]).¹⁰⁴ A South African study found HBoV in 49 of 517 (10%) HIV-infected and 125 of 943 (13%) HIV-uninfected children hospitalized with lower respiratory illness.¹²⁰

A recent study tested monthly saliva specimens collected from 87 children followed from birth to 18 months of age.¹¹² Almost all children

had HBoV detected at least once, and 66 (76%) had a primary detection event. Primary detection was statistically associated with the presence of new cough symptoms within 14 days, though this included the 7 days prior to HBoV detection. This association was stronger when restricted to those with a high viral load, supporting some studies that link viral load with clinical disease (discussed later).

Most published studies include only patients with symptomatic respiratory illness, while those including asymptomatic controls offer conflicting findings. Several studies reported lower rates of HBoV detection in controls compared to cases with respiratory illness.^{2,55,83,107} However, most of the controls were not well age matched or season matched, or they comprised different types of respiratory specimens collected from cases and controls. Large prospective studies in Canada, Denmark, and The Netherlands with age-matched and season-matched controls have found similar rates of HBoV in asymptomatic subjects and children with ARI.^{102,148,151} A prospective study in Thailand reported four-fold higher HBoV detection in all respiratory illness cases compared to controls. However, HBoV was not detected significantly more often in either hospitalized pneumonia cases or outpatients with influenza-like illness than in controls when considering only HBoV-positive patients without co-detection of other viruses and controlling for age and month.⁵² In a prospective 1-year cohort study of 119 daycare attendees, HBoV was detected in 20 (44%) of 45 asymptomatic subjects at enrollment.¹¹⁰ In a prospective pneumococcal vaccine trial cohort of 221 children in Papua New Guinea, HBoV was detected in 53 of 273 (19%) asymptomatic children and in 18 of 80 (22%) children with acute respiratory illness.²⁸ A prospective Swedish study of children hospitalized for community-acquired pneumonia found HBoV in 14 of 121 (15%) cases and 50 of 240 (21%) age-, gender-, and season-matched asymptomatic controls.¹³¹

HBoV is detected year round, though detection is more common during the winter months.^{2,6,9,30,52,54,55,83} It should be noted that this period is when most respiratory specimens are collected due to the seasonality of other acute respiratory viruses. HBoV infections are reported in immunocompromised hosts.^{21,39,74,91,136,137} HBoV was uncommon in adults with chronic obstructive pulmonary disease exacerbations.¹³³

Seroprevalence studies using diverse methods have reported seroprevalence of 74% to 99% among adults.^{47,58,63,68,71,75,76,96,99} A prospective serosurvey of 109 Finnish children found that all seroconverted by age 6 years.¹¹³ One factor that complicates the interpretation of prior seroepidemiology is the recent discovery of serologic cross-reactivity between HBoV1, HBoV2, HBoV3, and HBoV4.⁷⁶ This study used HBoV viruslike particles to deplete cross-reactive antibodies, and the investigators found that the seroprevalence of HBoV2, HBoV3, and HBoV4 in adults was 34%, 15%, and 2% and in children aged 1 to 2 years 25%, 10%, and 5%, respectively. The HBoV1 seroprevalence among adults decreased from 96% to 59% after depletion of HBoV2, HBoV3, and HBoV4-reactive antibodies. A similar Chinese study reported that the seroprevalence of HBoV1, HBoV2, HBoV3, and HBoV4 in adults was 67%, 49%, 39%, and 1%, respectively; in children, the seroprevalence was 50%, 37%, 29%, and 1%, respectively.⁶⁰ Thus, serologic data suggest that HBoV1 is the most frequent bocavirus type infecting humans.

PATHOGENESIS

The method of transmission of HBoV is not known. However, because the virus is present in the nasopharynx in high concentrations, a reasonable conclusion is that its spread is similar to that of other respiratory viruses.⁷⁰ This spread could involve contact transmission with droplet nuclei or by fomites. Parvovirus B19 can be transmitted via respiratory secretions.^{4,37,57} A few nosocomial infections have been reported.^{18,31,45,83} Parvoviruses are resistant to disinfectants, which could contribute to environmental persistence.⁴⁹

A unique feature of HBoV respiratory infections is the high frequency of mixed infections with other established pathogenic respiratory viruses. Several potential reasons for the high rates of co-detection have been postulated: bocavirus may be an asymptomatic passenger agent, function as a helper virus during respiratory viral co-infection, or be activated by inflammation induced by other viruses.¹³⁸ Studies have identified high rates of 20% to 90% co-infection with HBoV and other viruses, including influenza, human metapneumovirus (MPV), parainfluenza viruses (PIV),

and respiratory syncytial virus (RSV).^{*} Manning and colleagues¹⁰⁸ detected HBoV in 47 (8.2%) of 574 specimens from subjects with acute respiratory illness, 43% of which were co-infected with another virus. Co-infection with another virus—including influenza, PIV, or RSV—was detected in 90% of outpatients with influenza-like illness in Thailand.⁵² A prospective study of daycare attendees found another established respiratory virus in 72% of HBoV-positive acute respiratory infection episodes during the study.¹¹⁰ This high rate of co-detection of other viruses with HBoV is similar to other reports of 60% to 90% co-detection.^{2,15,19,35,52,69,102,122,148} The presence of established respiratory pathogens makes it difficult to assign a causal role to HBoV in these reports.

Several studies have shown an association between HBoV single infection and respiratory symptoms, and several suggest that a higher HBoV viral load in the nasopharynx correlates with symptomatic disease.^{17,33,56,72,83,95,124,156,157} Kantola and associates demonstrated the occurrence of IgM antibody responses and titer increases of IgG antibody in children with respiratory illnesses.⁷⁵ Concurrent detection of HBoV in nasopharyngeal samples and blood has also been suggested to correlate with acute respiratory illness.^{33,143} However, HBoV has also been detected in the serum of healthy blood donors.^{14,96}

Another unusual feature of HBoV is prolonged shedding and intermittent detection of HBoV over weeks to months.^{12,17,95,151} Martin and colleagues¹¹⁰ documented prolonged shedding (up to 75 days) in 20 subjects, with intermittent detection several months apart in 18 other children. However, prolonged shedding was not detected during single HBoV infections but only during co-infections with other viruses, suggesting that HBoV may cause either acute short-term infection or a more indolent long-shedding infection.¹¹¹ The aforementioned longitudinal saliva specimen study from the same group reported a median duration of HBoV shedding of 50 days, with a maximum of 402 days.¹¹² Several groups detected HBoV in tonsil and adenoid tissues from surgical specimens, suggesting long-term persistence.^{32,36,39,103,123,126,127} Interestingly, the rates of detection were higher in adenoids (24–56%) than tonsils (5–16%). Moreover, HBoV mRNA was detected, indicating active viral replication, and viral mRNA correlated with the detection of HBoV DNA in blood.¹²⁶ One study detected HBoV in 18 of 102 (18%) sinus mucosal biopsy specimens from patients with histories of chronic sinusitis but without acute illnesses; 17 of these had HBoV-negative nasopharyngeal swabs and blood.⁵⁰ Prolonged detection of HBoV in stool has been reported,^{82,136} and HBoV can persist as episomal DNA within gastrointestinal tissue.⁷⁸ Thus, prolonged detection of HBoV in humans appears to reflect the viral capacity to establish persistent infection, though the compartment, mechanisms, and nature of this infection are not clear.

HBoV is rarely detected in other tissues. HBoV DNA has been detected in heart tissue from patients undergoing cardiac surgery without evidence of virus-associated cardiomyopathy.⁹⁰ HBoV has not been associated with any systemic illness or anemia. HBoV has not been detected in amniotic fluid or fetal tissues,^{46,132} in contrast to BPV, MVC, and B19, which can cause intrauterine infections in animals or humans.^{65,109} HBoV was not detected in skin or synovial tissues.¹¹⁹

CLINICAL MANIFESTATIONS

Respiratory Illness

HBoV has been detected in nasopharyngeal specimens from children with both upper and lower respiratory tract illnesses. Most studies focus on hospitalized cohorts with predominantly lower tract disease. Many investigations have compared the signs and symptoms associated with HBoV infection with those caused by other respiratory viruses.[†] These comparative studies show that the clinical findings associated with HBoV infections are similar to those of viral infections caused by RSV, MPV, adenoviruses, influenza viruses, PIV, and rhinoviruses. Laboratory findings associated with HBoV infection are non-specific. White blood cell counts ranged from 3000 to 31,000 cells/mm³ in several studies, with means of 11 to 14,000, while C-reactive protein levels ranged from 0.2 to 11.4 mg/dL with median values of 0.4 to 1.2 mg/dL.^{6,106,150}

Upper Respiratory Tract Infections

In one study, 86% of 49 HBoV infections without co-infection with other agents were classified as upper respiratory illnesses.⁴⁸ In contrast, only 42% of 50 children in this study who had HBoV and a co-infecting virus were diagnosed with an upper respiratory illness. Pharyngitis was observed in 55% of the cases in which HBoV was the single agent identified. Of the children with HBoV infections without co-infections, 18% had acute otitis media and 12% had sinusitis. In another study, otitis media was reported in 61% of all HBoV infections.¹⁰²

In a large study, Arnold and associates⁶ noted the following findings at the time of presentation: fever, 68%; rhinorrhea, 67%; cough, 85%; conjunctivitis, 7%; vomiting, 30%; diarrhea, 21%; and rash, 7%. Of interest was that the cough was paroxysmal in 19% of the HBoV-infected children, whereas paroxysmal cough was much less common in adenovirus infections (7%) and MPV infections (5%).

In one Korean study, three of 36 (8.3%) children infected with HBoV had croup.³⁰ In a study in Canada, two of 58 (3%) HBoV-infected children had croup,¹⁰ and in a study in Japan, one of 18 (6%) had laryngotracheitis.¹⁰⁶

Lower Respiratory Tract Infections

Longtin and colleagues¹⁰² noted that 42% of children with HBoV infections had pneumonia and that 42% had bronchiolitis. In a large study in San Diego, California, involving 82 children with HBoV infections, 76 children with adenoviral infections, and 87 children with MPV infections, the investigators were able to compare the rates of various clinical findings.⁷ In this study, the following rates of events were noted in HBoV-infected children: hospitalization, 69%; need for oxygen administration, 44%; admission to intensive care unit, 11%; intubation, 4%; clinical lower respiratory tract disease, 61%; hypoxia, 41%; increased work of breathing, 59%; abnormal lung findings, 51%; “atelectasis versus infiltrate,” 11%; “infiltrate” or “pneumonia,” 9%; and bronchiolitis, 46%. Comparatively, adenovirus-infected children had less lower respiratory tract disease, less hypoxia, less increased work of breathing, and they were more likely to have normal chest radiographic findings than were children with HBoV and MPV infections.

In a study in Korea, 53% of HBoV-infected children had rales noted on chest auscultation and 42% had wheezing.³⁰ The clinical diagnoses in this study were bronchiolitis (25%), pneumonia (56%), exacerbation of asthma (11%), and croup (8%). In a study in Germany, 32 children with lower respiratory tract disease were studied.¹⁵² The diagnoses were bronchitis (16%), wheezing bronchitis (14%), bronchiolitis (3%), and pneumonia (18%). Ten of the 11 patients in this study with pneumonia had co-infections with other respiratory viruses. In a study in Canada involving 58 bocavirus infections, 40% had bronchiolitis and 22% had pneumonia.¹⁰ In a study of 18 children in Japan, the lower respiratory tract diagnoses were wheezy bronchitis (33%), pneumonia (33%), bronchiolitis (11%), bronchitis (11%), and asthmatic attack (6%).¹⁰⁶

Gastrointestinal Illness

Gastroenteritis has been associated with HBoV infections, and HBoV has been detected in stool^{92,93,149,154} by PCR, but the biological significance of this is not clear. Similar to the acute respiratory infection data, established gastrointestinal pathogens are co-detected frequently with HBoV, and HBoV is detected in stool specimens from asymptomatic subjects.^{8,81,118,134} In one study in Hong Kong, diarrhea was noted in 11% of 79 patients with respiratory symptoms.⁹² In the same study, HBoV was identified in fecal samples of 25 children with gastroenteritis. Of these children, 16% had blood in the stool, 8% had mucus in the stool, 32% had vomiting, and 68% had fever. The following respiratory findings were noted in these children with gastroenteritis: coryza (56%), acute bronchitis (16%), and pneumonia (12%). Co-pathogens were identified in 56% of the children: rotavirus (36%), *Salmonella* spp. (8%), *Campylobacter* spp. (4%), *Staphylococcus aureus* (4%), and *Clostridium difficile* (4%).

In a study of 962 stool samples from children with acute gastroenteritis in Seoul, Korea, a viral agent was found in 44.4% of the specimens, including rotavirus (25.7%), norovirus (13.7%), adenovirus (3.0%), astrovirus (1.1%), and HBoV (0.8%).⁹³ In Brazilian children with gastroenteritis, HBoV1 was detected in 2% to 10% of stool samples, often with other viruses,

and viral load did not correlate with disease.^{1,125} One study detected HBoV1 in 12% in asymptomatic South Korean subjects.⁸⁶

Several studies suggest that the newer bocaviruses HBoV2, HBoV3, and HBoV4, which were discovered in stool specimens, may be more likely to be associated with diarrhea than HBoV1.^{8,22,62,67,81,85,118,134,146} HBoV2 is the most frequent type detected in stool from gastroenteritis at 3% to 5%, but in several studies, it is detected at similar rates in asymptomatic controls.^{27,81,118,134,154} A study of Finnish subjects with acute respiratory illness with or without gastroenteritis symptoms found that HBoV1 to HBoV3 were not associated with gastrointestinal illness.¹²¹

Infections in Immunocompromised Patients

Koskenvuo and associates⁸⁹ described three children with acute lymphoblastic leukemia with detection of HBoV in respiratory specimens collected during acute febrile illness. In addition to fever, one of these children had cough, rhinitis, and otitis media, and another child had vomiting and diarrhea. The third child had five consecutive febrile episodes during the course of a 6-month period; with each of these episodes, HBoV was found in nasal swab samples. Another report described prolonged detection of HBoV for up to 3 months in children with various immunodeficiencies.¹³⁶ Other cases of HBoV infection in immunosuppressed children and adults have been reported, none fatal.^{6,21,39,74,91,107,108,137,142} A series of 53 pediatric stem cell transplant recipients testing only serum specimens found no episodes of HBoV viremia.¹²⁹

Other Clinical Findings

In addition to respiratory and gastrointestinal signs and symptoms, numerous other clinical findings and diagnoses have been observed in children with HBoV infections. Arnold and colleagues⁶ noted four children with maculopapular erythematous rashes, and exanthems have been noted in other studies.^{34,92,116} In three studies, the rate of exanthema varied between 5% and 9% in the children studied.

Three studies detected HBoV in respiratory or fecal samples from children clinically thought to have Kawasaki disease (KD).^{7,24,92} However, a case-control study of 12 children with KD and 33 age- and gender-matched controls found equal serum levels of HBoV-specific IgA and IgG in both groups, while none in either group was HBoV IgM-positive.⁹⁴ None of the KD cases and only one control had HBoV DNA in the serum. Another study performed HBoV PCR on endothelial cells from 22 cases of KD, including 18 with coronary artery lesions; none was positive for HBoV.¹⁶

Other events noted in temporal association with HBoV infection include intussusception,^{23,92} aseptic meningitis,⁹² and nephritic syndrome.⁹² There are isolated reports of HBoV DNA detection in the cerebrospinal fluid of patients with encephalitis, but the biologic and clinical implications of this finding are not clear.^{114,115,153}

DIAGNOSIS

Differential Diagnosis

The clinical features of HBoV respiratory infections are similar to those of other common respiratory viruses, including adenovirus, influenza virus, MPV, PIV, rhinovirus, and RSV. Similarly, gastroenteritis associated with HBoV infection cannot be differentiated from rotavirus infections and illness associated with other viral and bacterial agents.

Specific Diagnosis

Presently, the only diagnostic method for the demonstration of HBoV infection is PCR. Specimens for PCR may be obtained from respiratory secretions, stool, and blood. Primer sets used target the NP1 region 4 and the NS1 region of the genome.^{3,141} A real-time PCR assay targeting the NS1 gene is capable of detecting all four known HBoV types.⁷⁷ Some commercially available multiplex molecular assays include HBoV.^{38,135}

Some authors argue that serodiagnosis, the measurement of HBoV viral load, or a combination of serologic testing and blood PCR provides a more accurate diagnosis of acute infection versus asymptomatic shedding.^{33,75,88,113,140,143} Some studies report confirmation of primary HBoV infection using paired acute and convalescent sera, which would

not be useful during an acute illness.^{44,75,113,117,143} There are no commercial reagents for serodiagnosis of HBoV at present.

TREATMENT

No specific antiviral treatment for HBoV infections is known. General care should be similar to that employed for other respiratory or gastrointestinal viral infections. Humans develop CD4⁺ T-cell and antibody responses against HBoV.^{100,101,143} Moreover, antigenic epitopes on the HBoV capsid have been identified using monoclonal antibodies, and recombinant virus-like particles were immunogenic in mice.^{40,73} Thus, the potential for vaccine development exists if warranted.

PROGNOSIS

Although the full spectrum of HBoV infections and possible sequelae are not known presently, nearly all HBoV infections appear to be self-limited. There are rare reports of severe disease or fatalities in persons with chronic underlying conditions.

Human Polyomaviruses

154

John A. Vanchiere

The human polyomaviruses are a diverse group of viruses that are believed to have existed in the human population for thousands of years, but their ability to cause disease in modern humans is largely limited to opportunistic diseases in severely immunocompromised patients. The acquired immunodeficiency syndrome (AIDS) epidemic and increasing use of immunosuppressive therapies for the treatment of oncologic, neurologic, autoimmune, and rheumatologic disorders brought the family of *Polyomaviridae* to the foreground of biomedical science since the 1980s. With the increasing use of deep-sequencing methods, numerous human polyomaviruses with unique tissue tropisms have been detected since 2000, highlighting the need to understand the natural history and disease potential of these diverse agents. While the polyomaviruses derive their name from “poly,” meaning many, and “oma,” which refers to their ability to induce tumors in laboratory animals, the story of their emergence as opportunistic causes of both malignant and nonmalignant diseases is continuing to unfold. Their colorful history and critical role in the elucidation of fundamental cellular and molecular pathways has immortalized them as research tools.

HISTORY

The recognition of progressive multifocal leukoencephalopathy (PML) as a clinical entity in 1958 marks the beginning of our knowledge of the human polyomaviruses.¹⁶ Richardson and colleagues described three cases of progressive neurologic disease in patients receiving chemotherapy for leukemia. At autopsy, they found many foci of demyelination, including oligodendrocytes with intranuclear inclusions and astrocytes that were enlarged with bizarre nuclear changes, defining the classic histopathologic features of PML.¹⁶ Richardson subsequently reported a larger series of PML cases and proposed a viral etiology associated with immunosuppression.¹⁷⁶ In 1965, papovavirus-like particles were observed by electron microscopy of brain tissue from patients with PML and, in 1971, JC virus (JCV) was isolated from primary human fetal glial cell cultures that had been inoculated with a brain extract from a patient with PML.^{158,239} In the same year, another human polyomavirus, BK virus (BKV), was cultivated from the urine of a renal transplant patient.⁷³ Each virus was named with the initials of the patient from whom it was isolated.

Between 2000 and 2015, 11 additional human polyomaviruses were discovered, each with unique features that have challenged our understanding of polyomavirus biology. The respiratory polyomaviruses, KI polyomavirus (KIPyV) and WU polyomavirus (WUPyV), were discovered in 2007 by interrogation of respiratory secretions using deep-sequencing methods.^{4,74,91,155} The St. Louis and Malawi polyomaviruses were discovered in fecal specimens and have also been detected in tonsil tissue, but no clinical disease has been associated with these unique viruses.^{134,154,165} The visualization of the trichodysplasia spinulosa polyomavirus (TSPyV) by electron microscopy marked the beginning of the characterization of cutaneous polyomaviruses in the human population, an area of intense study due to the more recent discovery of the Merkel cell polyomavirus (MCPyV) and several additional cutaneous polyomaviruses in the human population.^{65,183,197,220,221}

Simian virus 40 (SV40), the prototype polyomavirus, was isolated in 1960 by Sweet and Hilleman as a contaminant of secondary rhesus monkey kidney cell cultures that were used to produce early polio vaccines.²⁰⁹ Additionally, several early adenovirus vaccines and a

respiratory syncytial virus vaccine were contaminated with SV40.^{131,148} Although rhesus monkey kidney cells showed no cytopathic effect, when supernatants from vaccine cultures were used to inoculate green monkey kidney cells, a pronounced cytopathic effect was observed, thus giving rise to the original name of SV40, vacuolating virus. By that time, millions of doses of both live and killed preparations of polio vaccine containing SV40 had been given to humans in the United States and Europe. Soon after its identification, the demonstration that SV40 induced tumors in neonatal rodents prompted great concern about its potential effects in humans.⁸³ Serologic studies showed that the formaldehyde-inactivated Salk poliovirus vaccine, but not the live-attenuated Sabin poliovirus vaccine, induced high-titer, SV40-specific antibody responses.⁷⁶ Although the live-attenuated poliovirus vaccine preparations contained higher titers of infectious SV40 virus, they failed to induce virus-specific antibodies in vaccinees despite prolonged shedding in stool.¹⁴⁴ A 30-year follow-up of infants possibly exposed to SV40 between 1955 and 1962 via inactivated poliovirus vaccine preparations showed no excess risk of cancer, but such epidemiologic studies have significant limitations.^{64,203,205} Despite numerous reports of the detection of SV40 in human tumors, tissues, and excretions, whether SV40 is the cause of human diseases—including malignancies—remains controversial.³³ Since the 1960s, the mechanism of SV40-induced tumorigenesis has been intensely studied and, as a result of SV40-related research, many facets of cell and molecular biology have been elucidated, including transcriptional regulation, alternative splicing, eukaryotic DNA replication, tumor suppressor proteins, nuclear localization signals, and viral effects on cell cycle control.⁴⁵

VIROLOGY

Polyomaviruses are classified in the family *Polyomaviridae*, which has been separated into four genera: *Alphapolyomaviruses*, *Betapolyomaviruses*, *Gammapolyomaviruses*, and *Deltapolyomaviruses*. More than 100 polyomaviruses are now known, each with a limited host range in which one or several closely related species can be infected.^{204,223} Primate, rodent, and avian polyomaviruses are the most studied members of the family *Polyomaviridae*, but the rapid detection of unique polyomaviruses in other species may offer unique insights into viral evolution and virus-host coevolution that could challenge long-held concepts. Based on their similar genomic structure and replication strategies, it is likely that the polyomaviruses and papillomaviruses evolved from a common progenitor virus. Human polyomaviruses are 45 nm in diameter with a genome approximately 5200 base pairs in length; papillomaviruses are somewhat larger, 55 nm in diameter with a genome approximately 8000 base pairs in length. The genomic organization of the polyomaviruses and papillomaviruses differs in that polyomaviruses use both DNA strands to encode proteins, whereas papillomaviruses use just one DNA strand. Viruses in both families cause infection in immunocompetent and immunodeficient hosts and also have been associated with malignancies.

Based on their tissues' tropisms, the human polyomaviruses can be divided into three groups: a nephrotropic group, including JCV and BKV; a respiratory group, including WUPyV and KIPyV; and a cutaneous group, including TdSPyV, MCPyV, and other cutaneous PyVs (Table 154.1). Among the nephrotropic human polyomaviruses, the nucleotide sequence of JCV has approximately 75% overall homology with BKV and 69% homology with SV40.⁴⁵ WU and KI are distant outliers among

TABLE 154.1 Human Polyomviruses

the primate polyomaviruses, sharing only 30% to 40% nucleotide identity with BKV and JCV in the late region. Despite the high degree of divergence of the respiratory polyomaviruses from the nephrotropic polyomaviruses, both of these subgroups are members of the genus *Betapolyomavirus*.³⁷ In contrast, the MCPyV and several other cutaneous polyomaviruses (HPyV-8, -9, -12, and -13) are more closely related to nonhuman primate and rodent polyomaviruses, whereas the STL and MW polyomaviruses cluster among *Deltapolyomavirus* with bovine polyomaviruses.^{37,65,223}

Several decades of studies of the biology of BKV, JCV, and SV40 have contributed to the current understanding of the biology of human polyomaviruses, principles of which may be challenged by ongoing studies of the more recently identified respiratory and cutaneous polyomaviruses that apparently lack a regulatory agnoprotein gene.^{80,223} All polyomaviruses share a characteristic circular genome that can be divided into structural, nonstructural, and regulatory regions. The structural (late) region of the viral genome encodes VP1, VP2, and VP3, the capsid proteins that envelop the viral genome. VP1 is the major capsid protein, accounting for more than 70% of the virion mass; it participates in host-cell recognition and stimulation of the host immune response. VP2 and VP3 are smaller, less abundant capsid proteins. The nonstructural (early) region of the polyomavirus genome encodes the large T antigen, the best studied of the polyomavirus proteins; this protein initiates viral DNA replication, stimulates cellular entry into S phase, and influences cellular and viral transcription. The small t antigen is produced by alternative splicing of the early viral mRNA and promotes G₁ cell cycle progression; it is not required for viral growth in cultured cells. The large T antigen of SV40 is responsible for the transformation of cells in vivo and in vitro, but the T antigens of other primate polyomaviruses are generally less adept at eliciting transformation. The large T antigen is a multifunctional protein that contains binding sites for the cellular pRb and p53 proteins. By binding to pRb, the large T antigen allows E2F-mediated progression of the cell cycle, thus providing the right environment for replication of viral DNA. Through its association with p53, a cellular tumor suppressor protein, the large T antigen blocks p53-induced cellular gene expression, thereby leading to genomic instability.³² In addition to its interaction with host proteins, the large T antigen has enzymatic activities that may be useful sites for targeting antiviral compounds.¹⁸⁸ Similarly, the large T antigens of JCV and BKV can interact with a variety of cellular proteins, including the p53 and pRb family proteins.¹⁰³ The large T antigen of MCPyV has been shown to interact with pRB but not p107 or p130 proteins, and the genome

of MCPyV is frequently found integrated into the genome of Merkel cell carcinomas.^{65,95} The regulatory region of the polyomavirus genome contains both the origin of replication and the viral promoter. The origin is recognized by the large T antigen, in concert with host-cell factors, including cellular DNA polymerase, and viral DNA replication is initiated. Both early and late viral transcription is mediated by cellular RNA polymerase. T antigen binding to viral DNA autoregulates the production of early mRNA and, by interaction with cellular factors, stimulates late transcription. Polyomaviruses have either an archetypal (single-enhancer) or rearranged (complex) regulatory region that can alter the efficiency of virus replication in vitro.^{30,32,85,103}

Variants of BKV and JCV with complex regulatory regions are common in immunocompromised patients and, at least for JCV in PML, these variants are considered the pathogenic virus.⁶⁶ While regulatory region variants of BKV may impact viral replication in vitro, there is no clear evidence that such changes are necessary or sufficient for the pathogenesis of BK virus–associated nephropathy (BKVAN) in at-risk patients.³⁰ Recent data on the virology of PML-associated strains of JCV suggests that mutations in the viral coat proteins may alter the tissue tropism of JCV and facilitate its dissemination into the central nervous system.⁸⁴ Another important advance in the current understanding of polyomavirus replication has been the discovery of virus-produced micro-RNAs that regulate gene expression and may play a role in the immunologic control of polyomavirus persistence.²⁰⁶ The clinical importance of this novel regulatory mechanism in the pathogenesis of polyomavirus-associated diseases is an area of intense investigation that may soon provide new targets for therapeutic intervention.^{41,42}

EPIDEMIOLOGY

Polyomaviruses are ubiquitous in the human population, and the prevalence of virus-specific antibodies increases with age, beginning in early childhood. BKV seroconversion occurs in 50% of children by the time they reach the age of 3 to 4 years.^{157,191} Population-based seroprevalence data suggest that more than 80% of adults have been infected with BKV.^{111,232} In contrast to earlier data, recent studies suggest that only about 50% to 70% of the adult population has been infected with JCV.^{5,27,68,111,116,157,166,191,217,232} BKV seroconversion has been associated with mild upper respiratory tract illnesses in a small number of children, and BKV viruria has been reported in a child with acute tonsillitis.^{87,207} To date, no distinct clinical syndrome has been associated with BKV infection of healthy children. The prevalence of antibodies in humans directed against SV40 has not been well established, primarily due to the variability in methods used by different research laboratories. Several studies have reported seroprevalences of 2% to 11% for SV40 using a plaque neutralization assay.^{34,36,179} However, other studies have suggested that much SV40 reactivity may be due to cross-reactivity with BKV.^{39,116,171,233} Whether BKV-reactive antibodies provide significant cross-protection against SV40 infection (or vice versa) has not been determined. As with the nephrotropic human polyomaviruses, the seroprevalence data for the respiratory and cutaneous polyomaviruses suggests that these viruses are ubiquitous in the human population, with infections occurring throughout life and more than 70% of humans having detectable specific antibodies to MCPyV, WUPyV, KIPyV, STL-PyV and MW-PyV.^{24,43,111,133,222,232}

Humans are the only known reservoir for JCV and BKV, which persist in the kidney, uroepithelium, and gastrointestinal tract.^{12,15,54,139,175,218,224–226} Their persistence in other organ systems is less certain but may include B lymphocytes and oligodendrocytes.^{20,55,59,123} The exact mechanism of transmission of JCV and BKV is not known, but several studies have shown that fecal excretion of BKV may be common in infancy and adulthood, suggesting that fecal-oral transmission could explain the ubiquity of early childhood infection.^{225–227} As described earlier, SV40 was introduced inadvertently into humans as a contaminant of early polio vaccines; however, such direct exposure cannot account for the SV40 seropositivity in children born more recently than 1962, suggesting continued human-to-human spread of the virus, albeit at low levels. In the pediatric population, one SV40 seroprevalence survey found nearly 6% of hospitalized children with antibodies to SV40.³⁵ Among kidney transplant patients in the cohort, 40% had

evidence of SV40 infection, but whether such infection was related to immunosuppressive medications or the underlying kidney disease was not clear.³⁵ SV40 DNA sequences have been detected in kidney tissue from several pediatric renal transplant recipients and in tonsil tissue from immunocompetent children.^{35,164}

In immunocompetent individuals, persistence of JCV and BKV in the kidney and uroepithelium is asymptomatic, and point prevalence studies suggest that intermittent shedding of JCV in urine is more common than shedding of BKV.^{2,192} Viral DNA (JCV or BKV) can be found in 30% to 50% of kidney samples from immunocompetent adults taken at surgery or autopsy.^{44,93,216} The frequency of JCV excretion in urine increases with age, while the prevalence of BKV excretion is approximately 2% to 5% in healthy adults.^{54,60,115} Recent data from a longitudinal study suggest that BKV excretion may be more common than previously thought, having been detected in over 19% of specimens collected daily from 7 of 20 women over a 2-month period.¹¹³

JCV is lymphotropic, and the finding of JCV in plasma and peripheral blood mononuclear cells generally correlates with immune status in that it is noted less frequently in immunocompetent patients and increases in frequency in HIV-infected patients with lower CD4 counts.^{52,72,117} Several conditions, including pregnancy and autoimmune disorders, are associated with excretion of BKV or JCV in urine.^{137,143,208,210,211} The immunologic and virologic factors regulating initiation and maintenance of persistence remain largely unknown.

CLINICAL MANIFESTATIONS

Central Nervous System Manifestations

PML is a clinical syndrome characterized by progressive neurologic impairment in severely immunocompromised patients. In PML, the host immune system fails to maintain viral latency, and acquired mutations in the VP1 and regulatory region of JCV facilitate neurotropism that leads to central nervous system invasion.^{66,84} JCV replicates in and lyses oligodendroglia and causes destruction of cerebral white matter in a multifocal or patchy distribution (Fig. 154.1). PML most commonly occurs in adult patients with AIDS, in whom approximately 5% will develop PML in the absence of antiretroviral therapy.^{19–21,89} Other immunosuppressed individuals who are at high risk for PML include patients receiving chemotherapy, solid organ or hematopoietic stem cell transplant (HSCT) recipients, and those with primary T-cell defects.

Numerous immunosuppressive agents used in the treatment of malignancies, autoimmune disease, and inflammatory disorders have been associated with an increased risk of PML, including rituximab, natalizumab, efalizumab, and others.^{18,25,38,119,160} For JCV-seropositive patients receiving natalizumab, the risk of PML is approximately 1% after 24 to 59 months of natalizumab treatment.²⁵ PML is rare in HIV-infected children compared to adults and has not been reported in association with monoclonal antibody therapies that predispose to PML in adults.^{23,202} At present, serologic testing for JCV-specific IgG antibodies is the only clinical test that may be useful for risk stratification of patients receiving prolonged immunosuppression. In addition to JCV seropositivity, both the duration of natalizumab therapy and a history of prior immunosuppressant therapy were associated with increased risk of PML among multiple sclerosis patients.²⁵ PML has also been reported in patients with relatively mild immunosuppression and without any known immunocompromise, although such cases are rare.⁸¹

Clinical manifestations of PML can include behavior changes; blindness, deafness, and other cranial nerve dysfunctions; motor and cognitive deficits; and incoordination as a result of cerebellar involvement.²² The onset of symptoms usually is insidious, and associated systemic signs such as fever and headache are uncommon. Progression of symptoms occurs over a period of several weeks to months, and the condition is inevitably fatal. The diagnosis of PML is largely clinical and based on the history, physical examination, and characteristic findings on neuroimaging studies. Computed tomography and magnetic resonance imaging of the brain show focal demyelination and white matter edema with relative sparing of the gray matter. The magnetic resonance image of a child with AIDS and PML is shown in Fig. 154.1.¹⁴⁹ Cerebrospinal fluid (CSF) analysis is often normal in patients with PML, likely a result of impairment or depletion (or both) of T lymphocytes.²² BKV-associated neurologic disease has been reported in several AIDS patients, and BKV encephalitis has been reported in a patient without known immunodeficiency in association with polyomavirus seroconversion.^{28,219,234}

Urinary Tract Manifestations

Asymptomatic polyomaviruria is a common occurrence in immunocompetent adults and children.^{40,60,106,115,181,227} Hemorrhagic cystitis temporally associated with BKV viruria has been reported rarely in immunocompetent children, but no other nonmalignant diseases have

FIG. 154.1 (A) Contrast-enhanced computed tomography of a brain of a child with progressive multifocal leukoencephalopathy showing low-density, nonenhancing, right-sided cerebellar white matter lesion without a mass effect. (B) On T2-weighted magnetic resonance imaging (MRI), the lesion produces a high signal without a mass effect or edema. (C) The lesion gives a low signal on T1-weighted MRI and fails to enhance with intravenous contrast. (From Morriss MC, Rutstein RM, Rudy B, et al. Progressive multifocal leukoencephalopathy in an HIV-infected child. *Neuroradiology*. 1997;39:142–144.)

been linked to polyomavirus infection in immunocompetent children.¹⁸⁴ Urinary excretion of BKV occurs in about 20% to 40% of adult and pediatric renal transplant recipients, approximately one-third to one-half of whom may also have BK viremia.^{94,97,98,100,102} Posttransplant polyomaviruria is due predominantly to reactivation of latent infection, and limited data suggest that the reactivated virus is often donor derived, at least for kidney transplant recipients.²³⁰ Excretion of BKV usually begins in the first 2 to 3 months after transplantation. In renal transplant recipients, BKV viruria may be associated with ureteral ulceration and stenosis, sometimes requiring surgical intervention to prevent or relieve obstructive nephropathy. The prognostic significance of polyomavirus reactivation in renal transplant patients has become a topic of great interest, especially as managing immunosuppression has become more sophisticated.

BKV has emerged as the most common infectious cause of renal allograft failure and is increasingly identified as a cause of native-kidney dysfunction in nonrenal transplant recipients (Fig. 154.2).¹⁷ BKVAN affects 1% to 10% of renal transplant recipients, resulting in allograft loss for approximately 60% to 75% of those affected.¹⁹⁴ Initially, case reports linking polyomavirus infection and allograft failure identified BKV as a possible pathogen.^{152,163,170} Larger studies have since revealed the pathogenesis of BKVAN as well as the appropriate diagnostic and therapeutic strategies. Retrospective analyses have found that BKVAN may be more commonly associated with the use of tacrolimus and mycophenolate, but BKVAN has been reported in patients receiving other immunosuppressive agents and in nonkidney solid-organ transplant recipients.^{1,29} Molecular characterization of BKV isolates from patients with BKVAN has not identified particular strains of BKV that are more likely to cause BKVAN, but some data suggest that the donor is the source of BKV in many BKVAN cases.^{187,195} The role of host factors in the pathogenesis of BKVAN remains an area of intense investigation. Importantly, repeat renal transplantation after allograft loss due to BKVAN has been successful without increased risk of BKVAN in the second allograft.⁷⁵

Polyomaviruria, especially that involving BKV, is a common finding after HSCT, occurring in 50% to 80% of patients within 2 to 8 weeks after transplantation.^{7,14,190} BKV viruria is associated with hemorrhagic cystitis (BKV-HC) in 15% to 25% of adult and pediatric HSCT recipients.^{13,67,82,127–130} BKV-HC is both painful and distressing for HSCT patients, occasionally necessitating erythrocyte transfusions and, rarely, surgical intervention.^{82,118} For the majority of patients with BKV-HC, supportive care, including intravenous hydration and erythrocyte transfusions, is adequate management, as T-cell engraftment eventually

controls BKV replication and leads to resolution of symptoms. Adenovirus is an important, but less common, cause of hemorrhagic cystitis after HSCT.^{3,67,130}

Interstitial nephritis caused by BKV has been described in children with various immunodeficiencies, including hyperimmunoglobulin M immunodeficiency and AIDS.^{48,180} Renal dysfunction is a common finding in AIDS patients, but its etiology has only rarely been linked to polyomaviruses; one study found SV40 in kidney tissue from several AIDS patients with a collapsing variant of focal segmental glomerulosclerosis, but the pathogenesis of this disease remains uncertain.¹³² Several studies of Balkan endemic nephropathy have associated this enigmatic disease in Eastern Europe with polyomaviruses, but further study is needed to establish a causal link.^{151,201} One pediatric study observed an association between SV40 seropositivity and renal transplantation and detected SV40 sequences in renal biopsy specimens, suggesting a possible role for SV40 in pediatric renal disease.^{34,35}

Cutaneous Manifestations

The clinical manifestations of cutaneous polyomaviruses are evident almost exclusively in immunocompromised patients, especially among those with marked T-lymphocyte suppression. The association of Merkel cell carcinoma and HIV infection was first described in 2002, but it was not until deep-sequencing approaches were used that the causative agent, MCPyV, was discovered.⁶⁵ Numerous case series have now established that the MCPyV can be detected in more than 75% (range: 43%–100%) of Merkel cell carcinomas, including tumors in immunocompromised and immunocompetent patients.¹⁰ Mutations in the helix domain of the large T-antigen are commonly found in MCPyV strains from Merkel cell carcinomas and are believed to be necessary for the oncogenesis of MCPyV.¹⁹⁷ The role of individual immunoresponses to MCPyV in the pathogenesis of Merkel cell carcinoma is an area of growing interest.²¹⁵ Trichodysplasia spinulosa due to TSPyV is predominantly a disease of severely immunocompromised patients, especially solid-organ transplant recipients and patients with hematologic malignancies.¹⁴¹ This striking disease is characterized by the eruption of erythematous papules with 1-mm to 3-mm keratotic spicules on the nose and chin, with occasional lesions on the trunk and back. In addition, patients often have eyelash and eyebrow loss.²¹² To date, approximately 20 cases of virus-associated trichodysplasia spinulosa have been reported in the medical literature.¹⁴¹ Other cutaneous polyomaviruses remain enigmatic. While they appear to be very common in the human population, they have not yet been associated with malignancy, and only the New Jersey polyomavirus has been associated with acute clinical disease. This unique alphapolyomavirus was the cause of vasculitis in an adult pancreas transplant recipient with neurologic symptoms and necrotic skin lesions.¹⁴⁷

Pulmonary Manifestations

While some contend that the nephrotropic polyomaviruses can be transmitted in respiratory secretions, there is little evidence to indicate that such transmission, if it does occur, is accompanied by clinical disease of the respiratory tract. Several case reports of BKV-associated pulmonary disease have been published, uniformly in the setting of severe immunosuppression and with poor outcomes.^{48,185,219,237} While interstitial pneumonitis in a patient with severe immunocompromise might raise the suspicion of polyomavirus-associated disease, other viral pathogens, such as cytomegalovirus (CMV) and adenovirus, should be considered more likely.

WUPyV and KIPyV can be found in upper and lower respiratory tract secretions from immunocompetent and immunocompromised patients, most often in association with other common respiratory tract pathogens.^{4,74,122} Numerous studies have documented that the clinical consequences of WUPyV and KIPyV are minimal, even in the most severely compromised patients.^{101,122}

Other Manifestations

BKV-associated retinal necrosis in an AIDS-infected patient has been described, as have elevated hepatic transaminase levels in association with BKV viruria and detection of BKV in normal liver specimens.^{28,92,114,156} The clinical significance of these manifestations is unknown.

FIG. 154.2 Immunohistochemical detection of the BK virus T antigen in kidney tissue obtained at autopsy from a pediatric patient with disseminated BK virus infection after hematopoietic stem cell transplantation (magnification $\times 40$). Arrows indicate positively stained renal tubular epithelial cells. (Courtesy J.A. Vanchiere, MD, PhD.)

Malignancies

The polyomaviruses are named for their ability to induce tumors in laboratory animals. Their association with human tumors was noted first in 1974 when Soriano and colleagues isolated SV40 from a metastatic malignant melanoma in a patient with SV40 neutralizing antibodies.¹⁹⁹ SV40 T antigen and capsid antigen were detected in lung, liver, and muscle metastases of the patient but not in normal tissue.¹⁹⁹ Since that time, polyomaviruses have been linked to a variety of neoplasms in humans, frequently analogous to the tumor types produced by SV40 in rodents. SV40 has been detected in association with human cancers much more frequently than have JCV and BKV. SV40 T antigen or DNA has been detected in a significant number of meningiomas, ependymomas, choroid plexus tumors, astrocytomas, pleural mesotheliomas, and osteosarcomas.^{11,104} Several studies reported the presence of SV40 in non-Hodgkin lymphomas.^{140,178,231} In the case of pleural mesotheliomas, which also have been associated with asbestos exposure, the presence of SV40 may be a negative prognostic indicator.¹⁶⁸ A possible synergistic effect of SV40 and asbestos has been observed *in vitro* and in case-control studies of human mesothelioma patients, suggesting that the two agents may work in concert as cocarcinogens.^{26,47,120} In one study of pediatric patients, JCV DNA was detected in 11 of 23 medulloblastomas, and JCV T-antigen expression was detected by immunohistochemistry in four of 16 samples tested.¹²¹ Other investigators have not detected polyomavirus DNA or protein expression in medulloblastoma tissue.^{112,150,236}

JCV has also been detected in colorectal and gastric cancers and in normal tissue samples from the human gastrointestinal tract.^{124,174,175} BKV has been detected in both normal and neoplastic prostate tissue, suggesting a potential role for BKV in the pathogenesis of this common cancer of adulthood.^{49,50} While Merkel cell carcinoma may be more common among immunocompromised patients, this neuroendocrine tumor occurs in immunocompetent patients as well, though very rarely in children.⁴⁶ Not surprisingly, immunocompromised patients tend to have poorer outcomes than immunocompetent patients. As such, the study of cutaneous diseases in immunocompromised patients is a growing area of research.^{136,147} Further studies, including evaluation of host immunogenetic factors, will be required to establish whether other polyomaviruses are commonly oncogenic in humans.

LABORATORY DIAGNOSIS

While the suspicion of polyomavirus disease is primarily a clinical one, laboratory techniques are important for making the diagnosis in the proper clinical circumstances. Serologic tests and viral culture are of little use clinically because these tests are laborious and rarely available. Furthermore, serologic data should be interpreted with caution in immunocompromised patients. Polyomaviruses in urine could be considered normal flora among immunocompetent patients, much like CMV detected in urine after infancy. Histologic study of urinary sediment can reveal “decoy cells,” which are uroepithelial cells with characteristic polyomavirus inclusions. The presence of decoy cells is a specific and moderately sensitive marker of polyomavirus-associated nephritis in renal transplant patients.^{56,58} Detection of specific polyomavirus DNA from urine samples is of little known significance, whereas polymerase chain reaction (PCR) detection from blood samples, especially viremia of greater than 10,000 genomes per milliliter, may correlate with the risk of BKVAN after solid-organ transplantation.^{126,153,169} Consensus guidelines suggest routine monitoring of kidney transplant recipients for BKV replication every 1 to 3 months for 1 to 2 years after transplantation, using either urine or plasma (preferred) quantitative PCR.^{99,110} Immunohistochemical detection of BKV T antigen in renal biopsy material is the gold standard for diagnosis of BKVAN, although electron microscopic identification of polyomavirus-like particles in renal biopsy material may also be diagnostic.^{38,135} The diagnosis of BKV-HC is based on clinical symptoms and the detection of BKV in urine, usually by PCR. Urinary viral loads in patients with BKV-HC and BKVAN can be extremely high, even 10^{12} or 10^{13} genome copies per milliliter.

Detection of JCV DNA in CSF by PCR is the diagnostic test of choice for suspected PML, although CSF PCR may be negative in some patients with PML.^{90,117,138,186} In adult patients with AIDS and neurologic

symptoms, PCR amplification of JCV DNA from CSF is 99% predictive of PML, whereas brain biopsy has a slightly lower sensitivity.⁵¹ Rare cases of PML with negative JCV PCR of the CSF have been reported.¹⁴² On gross examination, tissue typical of PML has been described as “worm eaten,” and microscopic examination reveals multiple foci of demyelination with enlarged oligodendroglia, giant astrocytes, and an intense phagocytic infiltration.²²⁹ Immunohistochemical techniques and other nucleic acid detection methods also can be used to confirm the diagnosis of PML.¹⁰⁷ JC viremia is a general indicator of immunosuppression and is a common finding in HIV-infected patients without PML; thus, its utility in the diagnosis of suspected PML is questionable.¹¹⁷

Detection of the cutaneous and respiratory polyomaviruses relies on PCR testing that is performed in research laboratories. With the exception of MCPyV and TdSPyV in immunocompromised patients, there are no clear clinical indications for pursuit of these viruses.¹²²

TREATMENT AND PREVENTION

No specific antiviral agents have been studied in randomized trials for the treatment of polyomavirus disease or polyomavirus-associated tumors. Studies in both adult and pediatric patients have demonstrated that routine monitoring of plasma BKV viral loads and preemptive reduction of immunosuppression are useful for the prevention of BKVAN without significant risk of allograft rejection, and routine screening for BKV has been recommended by international panels.^{99,110} Several studies have demonstrated the utility of frequent surveillance for reduction of the incidence of BKVAN.^{53,61} However, BKV reactivation may persist and lead to chronic renal dysfunction in some patients.²²⁸ BKVAN should be suspected in any renal transplant patient with otherwise unexplained allograft dysfunction. For renal transplant recipients with biopsy-proven BKVAN, reduction of immunosuppression may be helpful for preservation of allograft function, especially among patients with low-grade disease.^{57,71} The additional benefit of antiviral agents beyond that of reducing immunosuppression has not been established. Case series have reported variable results with the use of cidofovir and leflunomide in patients with BKVAN.^{8,9,63,108,109} Despite its potential nephrotoxicity, low-dose cidofovir has been suggested by an international consensus group as a potential investigational agent for treatment of BKVAN and is probably the most widely used antiviral for treatment of polyomavirus diseases.⁹⁸ Intravenous immunoglobulin has been used to treat several patients with BKVAN, with some authors reporting success and some not.^{6,189,196,235} A more recent report suggests that intravenous immunoglobulin is safe and effective for treatment of BKVAN in patients with inadequate response to leflunomide.¹⁹³ Both leflunomide and cidofovir have been used to treat HSCT recipients with particularly severe hemorrhagic cystitis and/or disseminated disease due to BKV, but immune restoration by T-cell engraftment is likely the most important factor in resolution of BKV-related cystitis. Despite numerous studies attesting to the ability of fluoroquinolone antibiotics to inhibit BKV *in vitro* and case series suggesting a potential clinical benefit, a well-designed clinical trial of levofloxacin for treatment of BKV viremia in adult kidney transplant recipients failed to demonstrate a benefit of levofloxacin compared to placebo.¹²⁵ However, an open-label study of ciprofloxacin and leflunomide in pediatric kidney transplant recipients suggests that this regimen may be advantageous.²³⁸ The prophylactic utility of ciprofloxacin for the prevention of BKV-HC after HSCT is suggested by an open-label study in adult HSCT recipients, but a controlled clinical trial for this indication has not been performed.^{70,146} Brincidofovir (formerly CMX001) is a lipid derivative of cidofovir that has *in vitro* activity against both BKV and JCV.^{86,177} Furthermore, this orally bioavailable agent is approximately 100 times more potent than cidofovir and has an improved safety profile *in vivo*.^{69,159} The use of brincidofovir has been reported in several pediatric and adult patients, and controlled clinical trials of its efficacy for the prevention of CMV disease after HSCT are ongoing.^{162,173}

Initiation of highly active antiretroviral therapy (HAART) can restore immune function and alleviate the symptoms of PML for AIDS patients.^{62,167,214} Despite administration of HAART, PML may develop in some HIV-infected patients due to incomplete immune reconstitution

or immune reconstitution inflammatory syndrome.^{198,213} Cidofovir has been used successfully in conjunction with HAART in patients with AIDS and PML, but its benefit above that of HAART and in non-AIDS patients with PML has not been determined.^{145,182} Though not reported in children, treatment of PML associated with immunomodulatory monoclonal antibody therapies should include consideration of plasmapheresis and/or the use of leukocyte colony-stimulating factors in order to promote restoration of immune function as quickly as possible. Consultation with research centers that study the pathogenesis and treatment of PML is advised, as the modalities being used vary greatly and may change frequently.^{105,200} Adoptive transfer of in vitro-stimulated, virus-specific, allogeneic cytotoxic T lymphocytes is a potentially promising prophylaxis and treatment option for patients after HSCT. This novel approach has been used successfully to prevent and treat Epstein-Barr virus-related disease after HSCT and may be useful for other viruses as well.^{77-79,96,161} Several potential immune-boosting vaccines for secondary prophylaxis against polyomavirus disease are in development.^{31,172} Given the ubiquity and generally benign nature of polyomavirus infections, as well as the paucity of information about the nature of their transmission and clinical significance in immunocompetent patients, specific efforts to prevent polyomavirus transmission are not indicated at this time. Universal precautions are appropriate for care of patients with polyomavirus disease.

Human Papillomaviruses

155

Adriana Cadilla • Kenneth A. Alexander

The human papillomaviruses (HPVs) are members of the virus family *Papillomaviridae*. More than 200 HPV genotypes have been identified. The double-stranded DNA genome of the HPV genome is approximately 8000 base pairs; intact virions are approximately 55 nm in diameter. Although most HPV infections are benign, HPVs can cause malignant transformation of squamous epithelia in both immunocompetent and immunodeficient hosts. HPVs also can cause a variety of benign cutaneous proliferations, including common skin warts. HPVs also have been associated with respiratory papillomatosis, which is a histologically benign but potentially life-threatening process. Our understanding of the complex role that HPVs play in these diverse clinical conditions remains incomplete, and management of these diseases remains an ongoing challenge. The licensure of two prophylactic vaccines against HPVs provides hope that the public health impact of these viruses will decrease.

HISTORY

Warts, or papillomas, have been recognized for centuries to occur at a variety of different body sites, in particular, the skin, genital tract, oral cavity, conjunctiva, and respiratory tract. The viral etiology of warts was demonstrated in 1907, when human volunteers were inoculated experimentally with a cell-free extract prepared from wart tissue.⁷¹ These early experiments also suggested that warts were transmissible from person to person. When electron microscopy became available in the 1940s, virus particles were visualized, initially in skin warts and subsequently in genital warts, thereby confirming the viral etiology of these lesions. However, despite the abundance of virus particles seen in some lesions, virologic investigation of HPV-associated disease processes was hampered by the inability to propagate papillomaviruses in either cell culture or laboratory animals. The limited amount of information available from the study of virus particles obtained directly from wart tissue led in the 1960s to speculation that HPVs were composed of a single virus type. Scientists further theorized that the specific body site and epithelium involved, rather than the virus type, were responsible for the characteristic morphology and disease process.²⁹⁹ With the advent of molecular biologic techniques in the 1970s, however, more than 70 different types of HPVs were described, and researchers quickly recognized that specific clinical diseases were associated with infection with specific HPV types. Most recently, HPV infection of the genital tract has been recognized as the most prevalent sexually transmitted infection, and a causal link between HPV infection and squamous carcinomas of the cervix is now well accepted. Challenges for the future revolve around developing effective treatment strategies because current measures are palliative at best and most lesions recur. New antiviral chemotherapeutic agents are being developed, and immunomodulators such as interferon provide promise for the treatment of serious disease caused by HPVs.

VIROLOGY

The family *Papillomaviridae* consists of small, nonenveloped viruses with a diameter of about 55 nm and includes the HPVs. *Papillomaviridae* viruses have a capsid composed of 72 capsomeres arranged in icosahedral symmetry. The papillomavirus genome is composed of double-stranded circular DNA that is approximately 8 kb in length. The complete nucleotide sequence is available for all clinically relevant HPVs, and partial sequence information is available for more than 120 HPV types.⁹¹ Sequence conservation between the many HPV types is substantial. The papillomavirus genome is divided into three regions: an early region that encodes the proteins required for viral replication (E1, E4), transcription control (E2), and cell transformation (E5, E6, E7; Table 155.1); a late region that encodes the viral major and minor capsid proteins (L1 and L2); and the viral long control region, which contains the origin of replication and many control elements for viral transcription and replication.^{111,135,193,269,270,271} The virus appears to replicate solely in the nucleus of the cell in association with low-molecular-weight histones.^{197,388}

Papillomaviruses display a high degree of species, tissue, and cellular specificity. HPVs appear to infect only humans; most animal papillomaviruses do not infect other species as well. Although all HPVs infect epithelial surfaces, each HPV type has a tropism for specific epithelia.^{124,352,380,381} The more than 200 HPV types that have been recognized may be classified according to the type of epithelia they infect (cutaneous or mucosal).²⁷³ The mucosal HPV types are further subclassified according to the oncogenic potential of each virus (Table 155.2). The common cutaneous HPV types are found in a variety of skin warts (e.g., palmar warts, plantar warts, flat warts) and are uniformly benign.^{35,36,279,350,372} The mucosal HPVs occur mainly in the anogenital tract but also infect and produce disease at mucosal sites in the respiratory tract, the oropharyngeal cavity, and the conjunctiva. The mucosal HPVs also are subgrouped into low-, high-, and intermediate- or moderate-risk types, depending on the frequency with which they are found in invasive cancers.^{30,202,304,340,367} A third group of HPVs cause cutaneous diseases in a small group of patients with epidermodysplasia verruciformis (EV, also known as Lewandowsky-Lutz dysplasia or Lutz-Lewandowsky epidermodysplasia verruciformis), an extremely rare autosomal recessive disorder marked by extreme warty growths, particularly on the skin of the extremities.²⁸² These EV-associated viruses (most commonly HPV types 5 and 8, but there are others) have variable oncogenic activity and can underlie the development of squamous tumors in sun-exposed areas.^{41,211,255,336,388}

The life cycle of HPVs is intimately entwined with the cell cycle and differentiation of epithelial cells.¹⁰⁵ HPV infection occurs after damage to the mucosa, allowing introduction of the virus into basal keratinocytes. Early infection is marked by E2 protein-regulated transcription of the viral early proteins. HPV infections are maintained in basal keratinocytes.

TABLE 155.1 Major Human Papillomavirus Genes

Gene	Protein Products and Function
Early (E) Region	
E1	Viral regulatory protein that initiates viral DNA replication
E2	Viral regulatory protein that controls replication and inhibits or activates early transcription of the viral genome
E3	Unknown
E4	A late viral protein that controls viral maturation; expressed in terminally differentiated keratinocytes
E5	Major transforming protein; causes cellular proliferation
E6	Major transforming oncoprotein; associates with the cellular target, TP53, a tumor suppressor protein, and promotes its proteolytic degradation; causes cellular proliferation and perturbation of keratinocyte differentiation
E7	Major transforming protein; associates with the cellular target pRB and inactivates its cell cycle restriction function; causes cellular proliferation and perturbation of keratinocyte differentiation
E8	Unknown; perhaps regulates viral DNA replication
Late (L) Region	
L1	Major structural viral capsid protein
L2	Minor structural viral capsid protein

Within basal keratinocytes, two forms of HPV DNA replication occur: maintenance replication and vegetative replication. Maintenance replication occurs in nondifferentiating basal keratinocytes at low levels sufficient only to ensure that HPV DNA is propagated to daughter keratinocytes; viral protein expression is minimal and limited to the viral early proteins. Vegetative replication occurs in differentiating keratinocytes as they enter the stratum spinosum. In the stratum spinosum, high-level viral replication occurs, with expression of the late proteins and production of complete virions. Progeny viruses are not released until fully differentiated keratinocytes are sloughed from the epithelial surface.^{239,377}

Interestingly, the HPV genome does not encode any viral DNA or RNA polymerase, rendering the virus wholly dependent on host enzymes for replication. In view of this absolute dependence on host cell DNA and RNA polymerases, replication of papillomaviruses must occur at a time in the host cell cycle during which cellular polymerases, replication factors, and nucleoside triphosphates are in abundance (i.e., S phase). To drive host cells from G0 into S phase, HPVs express the E6 and E7 oncoproteins. Although the E6 and E7 oncoproteins have many identified biochemical activities,^{305,358,379} the dominant activities of E6 and E7 are as follows. The E7 oncoprotein activates the cell cycle by displacing the E2F regulatory factor from the retinoblastoma tumor suppressor (pRB). This displacement of E2F from pRB allows E2F entry into the nucleus, where E2F activates genes that trigger cell cycle progression from G0 into S phase, with consequent activation of cellular (and viral) DNA replication. To attenuate the normal cellular protective response to unscheduled DNA replication (p53-induced cellular apoptosis), papillomaviruses express the E6 oncoprotein. The E6 oncoprotein forms a stable complex with the p53 tumor suppressor. This E6:p53 complex is then bound by the E6-associated protein (E6-AP), a ubiquitin ligase that, by ubiquitinating p53, earmarks p53 for destruction on the proteasome. By displacing E2F from pRB and by then degrading p53, papillomaviruses, in effect, “activate the engine” of cell proliferation and then “take away the brakes.” The oncogenic activity of HPVs lies largely with the E6 and E7 oncoproteins. Although E6 and E7 expression appear to be tightly regulated in HPV infection, HPVs can integrate, apparently at random, into the host cell genome, leading to unregulated E6 and E7 expression. Most, but not all, HPV-induced malignancies contain chromosomally integrated copies of the HPV genome.^{32,238,377}

Because full epithelial cell differentiation and keratinization of squamous epithelial cells are required for the HPVs to replicate completely, and because such differentiation is not achieved in conventional cell culture, HPVs cannot be propagated using standard tissue culture

methods. Limited propagation of HPVs in keratinocyte raft cultures that recapitulate the structure of a differentiating epithelium is now performed routinely in research laboratories but has no clinical application. Research laboratories have also propagated papillomaviruses successfully by inoculating virion extracts into susceptible tissue (typically human foreskins) and transplanting this tissue into athymic nude mice.^{167,184} Nonetheless, the laboratory and clinical study of HPVs and HPV-associated diseases has been and remains heavily dependent on the use of molecular biology techniques—in particular, polymerase chain reaction (PCR) assay.

EPIDEMIOLOGY

Among humans, HPVs are ubiquitous and, as a group, are the cause of the most common sexually transmitted infection. Although HPVs infect nearly all individuals of both sexes at some point in their lives, most infections are asymptomatic; only a minority of HPV infections come to medical attention. Even though a large proportion of HPV infection is subclinical and does not cause significant disease, the importance of HPV infection lies in the ability of HPVs to cause malignant transformation of squamous epithelial mucosal surfaces, potentially leading to significant cancer morbidity and mortality. Recently developed HPV vaccines have made important strides toward preventing HPV-associated neoplasias and malignancies.^{104,136}

HPVs are transmitted by direct skin-to-skin contact, with most sexually transmitted infection resulting from penetrative vaginal and/or anal intercourse. Other types of sexual contacts, such as oral sex, and even indirect genital contact, can also transmit the virus.^{136,387} Common body warts are transmitted by direct contact, often after minor skin trauma.²⁰⁰ There is also evidence of latent epithelial disease activation in immunocompromised individuals, including solid-organ transplant recipients and individuals with human immunodeficiency virus (HIV) infection.^{201,302,303} After vaginal births, HPV DNA can be detected in the mouths of up to 30% of neonates.^{55,292,351} Associations between the types of HPV DNA found in maternal and paternal oral and genital mucosa and that in infant’s oral mucosa have been made, although there is a high rate of HPV genotype discordance.^{69,176,240,258} Perinatal infection after vertical transmission during childbirth is implicated in recurrent respiratory papillomatosis (RRP) as well as hepatitis in some cases.^{98,264,317,392} There have been strong associations found between RRP in children and genital warts present in the mother at the time of delivery.^{2,55,349}

The incubation period for HPV infection varies greatly but is approximately 3 months.²⁰³ Nonetheless, disease can appear weeks to years after exposure, with invasive cancers typically developing after a decade or more.

It is estimated that, at any given time, nearly 20 million Americans are infected with HPV, with approximately 6 million new cases occurring each year, and about the same number of individuals clearing their infection each year. Most individuals with HPV infection do not show any signs or symptoms of infection; most infections are transient and cleared uneventfully, with median time to clearance of 8 months.¹⁵⁹ Seventy percent of infections are cleared by 12 months; more than 80% of genital HPV infections clear spontaneously by 24 months. HPV-16 is associated with increased persistence but still with a high rate (70%) of clearance within 24 months.^{18,68,159,177,234,294} For men and women, the lifetime risk for developing a genital HPV infection exceeds 50%; estimates are that 80% of individuals will have had a genital HPV infection by age 50 years. The highest rates of HPV infection are seen in females younger than 25 years old.^{51,166} Higher prevalence of HPV 6 and 11 is found in girls and young women 14 to 19 years old, whereas a higher prevalence of HPV 16 and 18 is found in those 20 to 24 years old.^{23,24,26,100,225,231,232,291} Most HPV infections are acquired within the first few years after sexual debut. Not surprisingly, the risk for HPV infection is proportional to the number of sexual contacts. Recently, however, data are emerging that indicate that normal adolescents who have never been sexually active can be infected with mucosal HPV types.^{94,162,326}

Other important risk factors for HPV infection include age older than 30 years, parity, smoking status, use of oral contraceptives, single marital status, and immunosuppression.^{56,161,298,300}

TABLE 155.2 Human Papillomavirus (HPV) Types and Associated Clinical Conditions

Condition	Usual Location	Morphology	HPV Type
Cutaneous (Skin) Warts			
Common (verruca vulgaris)	Hands, lips, extremities	Multiple, dome shaped	2, 4
Plantar (verruca plantaris)	Bottom of feet	Single, painful	1
Flat (verruca plana)	Arms, face, knees	Multiple	3, 10, 28, 41
Filiform	Face, neck	Multiple, threadlike	2, 4
Mosaic	Feet, hands	Multiple, superficial	7
Butcher's	Hands	Multiple, dome shaped	7
Epidermodysplasia verruciformis	Face, trunk, extremities	Multiple flat warts or reddish-brown plaques	5, 8, 9, 12, 14, 15, 17, 19–25, 36–38, 47, 49
Immunosuppressed patients	Face, trunk, extremities	Dome-shaped or epidermodysplasia verruciformis–like plaques; may be persistent or progressive	1–5, 8, 10, 20, 23, 28, 49
Mucosal (Anogenital) Warts			
Subclinical	Cervix	Asymptomatic	6, 11, 13, 16, 18, 30–35, 39, 40, 42–45, 51–59
Condylomata acuminata	Cervix, vulva, urethra, anus, penis, scrotum	Multiple exophytic, pink, gray	6, 11, 16
Flat condylomata	Cervix	Asymptomatic, flat plaques	6, 11, 16, 18, 31
Giant condylomata acuminata (Buschke-Löwenstein tumors)	Perirectal area	Large, tumorlike	6, 11
Bowenoid papulosis	Penis, vulva, perirectal area	Multiple, large	16
Cervical cancer	Cervix	Asymptomatic; pigmented papillomas; erythematous or white plaques; ulcerations; mass lesion	Strong association: 16, 18, 31, 45 Moderate association: 30, 33, 35, 39, 51, 52, 56, 58, 59, 68 Weak association: 6, 11, 26, 34, 40, 43, 44, 53–55, 57, 62, 66, 74
Vaginal cancer	Vagina	Asymptomatic; ulcerative mass lesions; vascular pattern with punctation and mosaicism	16
Vulvar cancer	Vulva	Asymptomatic; pigmented papillomas; erythematous or white plaques; ulcerations; mass lesion	16
Penile cancer	Penis	Painless, ulcerative mass lesion	16
Anal cancer	Perianal area, anal canal	Asymptomatic; pigmented papillomas; erythematous or white plaques; ulcerations; mass lesion	16, 18, 31
Ovarian cancer	Ovaries	Unknown	6?, 16?, 18?
Mucosal (Other) Warts			
Respiratory papillomatosis	Larynx, trachea, bronchi, lungs	Multiple papillomas	6, 11
Nasal and paranasal papillomas	Nose, paranasal sinuses	Single or multiple papillomas	6, 11, 57, 57b
Focal epithelial hyperplasia (Heck disease)	Oral cavity	Discrete, multiple nodules	13, 32
Oral cavity papillomas	Gums, buccal mucosa, soft palate, tonsils	Single or multiple papillomas	6, 11, 16
Conjunctival papillomas	Conjunctivae	Single or multiple papillomas	6, 11, 16
Giant cell hepatitis	Liver	Unknown	6?

The clinical presentation of HPV infection depends on the anatomic location and the type of HPV with which an individual is infected. Males and females infected with HPV experience similar clinical disease processes with related cutaneous warts while experiencing differing manifestations of anogenital condyloma and cancers based on anatomy. In both genders, rates of HPV-associated oropharyngeal and anogenital cancers are increasing.⁴⁵

The Centers for Disease Control and Prevention (CDC) estimates that, in the United States, nearly 30,000 cases of HPV-associated cancers occur annually, with two-thirds of those cases affecting females. Cervical cancer is the most common HPV-associated cancer overall; the second most common group of HPV-associated cancers comprises those of the oral cavity and the oropharynx. HPV-associated cancer rates vary greatly by state in both males and females, with higher rates (11 to 16/100,000) seen in southern, southeastern, and mideastern seaboard cities and states (e.g., Louisiana, Kentucky, Tennessee, and the District of Columbia). Rates of HPV-associated cancers in other parts of the country (e.g., Colorado, Utah, and Maryland) are lower (4 to 8/100,000).⁵⁹

Female-Specific HPV-Associated Malignancies

In females, HPV infections can progress to vulvar, vaginal, and cervical cancers. Persistent HPV infection is associated with increased risk for progressive epithelial pathologic process and cancer.

Although the incidence of cervical cancer has declined significantly in the United States in the past 50 years (largely through the development of universal cervical cytology screening programs), cervical cancer remains the second leading cause of cancer death in women worldwide, with more than 80% of cases occurring in the developing world.⁴⁰ Most cervical cancers are diagnosed in females older than 30 years. In contrast to vulvar and vaginal cancer, essentially all cervical cancer is HPV associated.^{59,359} In the United States, Hispanic (12/100,000) and black (10/100,000) females have higher rates of cervical cancer than females of all other races (7/100,000). Approximately 4000 females die annually of cervical cancer.^{19,59,359} Worldwide, the mortality to incidence ratio of cervical cancer is 52%. Globally, nearly 300,000 women die of cervical cancer each year, the majority of whom are in developing countries.^{260,325,378}

The most studied relationship between HPV and cancer risk is cervical cancer and its preceding grades of dysplasia.^{239,241,245,309,357} It is estimated that approximately 10% of all women in the world have a cervical HPV infection at any given time, with prevalence of infection being higher in the developing world. Some of the highest rates of infection are seen in Eastern Africa, whereas some of the lowest rates are seen in Southeast Asia. In all developed and developing countries, the prevalence of HPV infection is highest among young women; infection rates decline in younger middle-aged women, with a second resurgence of HPV infection in the perimenopausal age range. The cause for this perimenopausal resurgence of HPV infection phenomenon is not known but may be due to changes in sexual behaviors and acquisition of new HPV infection in middle age, reactivation of latent infection, or a high-exposure population promoting a cohort effect.^{157,180,188,245,283,284,344,345,347}

HPV-16 is the most common HPV type in cervical dysplasias and malignancies. HPV-18 is the second most prevalent, with some intercontinental variation seen between Europe, Asia, and the Americas.^{90,144,172} HPV-16 is the most oncogenic, responsible for nearly half of all cervical cancer. In women with invasive cervical cancer, HPV-16 and HPV-18 together contribute to approximately 70% of all cases.⁷⁴

Since 1986, in the United States, the rate of vulvar cancers has increased. In the United States, the overall incidence rate of vulvar cancers is 2.3 per 100,000 females. Each year, there are approximately 3000 new cases of vulvar cancer. Half of these cases are HPV associated.^{89,136,163} Worldwide, vulvar cancer contributes to approximately 4% of all gynecologic cancers.^{12,41}

Vaginal cancer is much rarer than vulvar cancer and occurs most often in females older than 80 years. In the United States, HPV-associated vaginal cancer cases account for over 700 (65%) new cases annually.⁷ Vaginal cancers affect black females (0.7/100,000) disproportionately more than females of all other races (~0.4/100,000).^{59,136}

Male-Specific HPV-Associated Malignancies

There are nearly 1700 new cases (and 250 deaths) of HPV-associated anal cancers diagnosed in males annually. Black males (1.6/100,000) are disproportionately more affected than males of all other races (0.2 to 1.0/100,000).^{59,136} Men who have sex with men are a unique population at high risk for persistent low- and high-grade anal lesions that can progress to invasive cancer.^{142,371}

Penile cancer is very rare and occurs most commonly in males older than 60 years of age. Approximately 1000 cases of penile cancer occur in the United States each year, of which 35% are believed to be HPV associated. Penile cancers affect Hispanic males (1.3/100,000) disproportionately more than males of all other ethnicities (0.7/100,000).^{59,136} The incidence of penile cancer is much lower than that of cervical cancer. Penile circumcision affords some degree of protection against penile cancers.

In addition to gender-specific HPV-associated invasive disease, other common HPV-associated disease processes, including cutaneous warts, anogenital warts, and oropharyngeal cancers, affect both sexes similarly.

A progressively higher prevalence of mucosal disease occurs in adolescence and young adulthood. In both males and females, anogenital warts (condylomata acuminata) occur in and around the genitalia and anus.¹⁴⁶ All anogenital warts are caused by HPV, with more than 90% caused by HPV types 6 and 11.¹⁴² Every year in the United States, there are approximately 1 million new cases of anogenital condylomata diagnosed, often first noticed within weeks or months of exposure. The majority of infections last longer than 4 months.¹⁸⁹ Individuals will have varying clinical courses, some with very few lesions lasting only a few months and some with progressive lesions increasing in size and number and causing significant morbidity.^{40,131,248}

HPV-Associated Malignancies in Males and Females

Similar to cervical cancer, nearly all new cases (90%) of anal cancer are HPV associated.⁶ In US women, there are 3000 new cases (and 500 deaths) of HPV-associated anal cancers annually. HPV-associated anal cancers affect white females (2/100,000) disproportionately more than females of all other races (0.4 to 1.4/100,000). The incidence of anal cancers in females in the general population is increasing at a rate of

nearly 2% per year.^{59,136} Among HPV-positive females, the prevalence of HPV-related anal cancers is even higher than that for cervical cancer.^{260,262}

HPV-Associated Oral and Oropharyngeal Cancers

Cancer of the oral and oropharyngeal cavities has gained increasing attention because its relationship to HPV infection has more recently been elucidated. HPV-16 DNA has been detected in up to 82% of head and neck cancers.²⁴⁴ Historically, oropharyngeal cancer risk has been associated with advanced age and with alcohol and tobacco use (alcohol- and tobacco-associated oropharyngeal cancers are often HPV negative). In contrast, HPV-associated oropharyngeal cancers occur in younger adults without strong histories of alcohol or tobacco use.

Although the incidence of non-HPV-associated oral and oropharyngeal cancers is declining, the incidence of HPV-associated cancers is increasing at a rate of approximately 5% per year.^{61,171} Among all oropharyngeal cancers, the prevalence rates of HPV-associated oropharyngeal cancers have risen from 33% of new cases in the 1980s to 70% in the 1990s and over 80% in the 2000s, particularly among white males.⁴⁶ In the United States, there are nearly 12,000 (60%) new HPV-associated oropharyngeal cancer cases annually. HPV-associated oral cancers affect males (9300 cases) more than females (2300 cases), with much lower rates found in Asian/Pacific Islander males (3/100,000) and females (0.5/100,000) compared with males and females of all other races (6/100,000 and 0.5/100,000, respectively).³⁵⁹ In the 1980s, HPV was associated with approximately 16.3% of oropharyngeal squamous cell carcinomas; in the 2000s, this number rose to 72.7%.⁶³ In the United States in 1999, the incidence of cancer in the oral cavity or pharynx was 6.4 per 100,000 for females and 16.3 per 100,000 for males; in 2013, the incidence in females was 6.3 per 100,000, and in males it was 17.4 per 100,000.³⁶¹

In both males and females, the incidence of HPV-associated oral and oropharyngeal cancers increases dramatically after 50 years of age.^{47,136,209} Those at increased risk for developing HPV-associated head and neck cancer compared with those with HPV-negative disease are generally white, younger, and of a higher socioeconomic status and have a higher education and more lifetime oral sex partners.^{21,137}

HPV-associated malignancies likely arise as an unusual consequence of oral HPV infection. The prevalence of oral HPV infection is estimated to be between 2% and 3% of young adults (18–30 years old).²⁷⁵ Those with concurrent HIV infection and those who are smokers have a higher prevalence of oral HPV.^{61,62,72,73} Even though white males experience the majority of HPV-associated oropharyngeal disease burden, they also show improved survival over females.²⁵⁴ Rates of HPV-associated oropharyngeal disease have increased so markedly within the past 20 years in the United States that by 2020 it is anticipated that the number of HPV-associated oropharyngeal cancers will exceed the number of incident cervical cancers.^{62,229}

HPV-associated head and neck cancers occur in younger persons (<60 years of age), with a preponderance of cases diagnosed in white males. In contrast, tobacco- and alcohol-related HPV-negative head and neck malignancies occur most frequently in older African American men.⁶³

A recent study determined that presence of HPV-16 in the oral cavity preceded incidence of oropharyngeal cancer.⁴ It remains unclear what effect HPV vaccine will have in head and neck cancer incidence, as it will take years for currently vaccinated children to reach the age at which head and neck cancer presents itself. However, it is speculated that the vaccine will afford protection, and a decline in head and neck cancer should occur.

HPV-Associated Malignancies in Persons With HIV

In 1993, the CDC added cervical cancer as an AIDS-defining malignancy. Since then, our understanding of the association between HPV malignancy and HIV has continued to grow. In the United States, the incidence of cervical cancer is two- to 22-fold greater among HIV-positive females than in HIV-negative females. Similarly, vulvar intraepithelial neoplasia has been reported to occur 29 times more frequently in HIV-positive women when compared with HIV-negative women.²⁹⁰ Most striking is the increasing incidence of anal cancer. The incidence of anal cancers

has been on the rise, with a yearly estimated increase of 1.7% among men. However, among HIV-positive men, the rise is greater, at 3.4% per year.⁴⁴

Penile cancer also seems to affect HIV-positive men more frequently than it does HIV-negative men, as HIV-positive men have a two- to threefold increased risk.²⁹⁰ Curiously, and in contrast with other AIDS-defining malignancies, there have not been decreases in the rates of HPV-associated malignancies in HIV-infected people despite the institution of highly active antiretroviral therapy (HAART). For example, pre-HAART (1992–95), the incidence of anal cancer among HIV-positive males and females was 19 per 100,000 person-years. This increased to 48 per 100,000 person-years post HAART (1996–99) and increased further to 78 per 100,000 person-years from 2000 to 2003.²⁵⁹ Ongoing studies are needed to better understand the association between HIV infection and HPV-associated malignancies. Current studies show conflicting results and no clear correlation between CD4 counts and the risk of HPV-associated malignancies. Improved universal screening guidelines are needed.

HPV and Sexual Abuse

The detection of mucosal (i.e., genital) HPV types in children may raise the suspicion of sexual abuse. Both vertical and horizontal transmission have been described (including perinatal transmission, heteroinoculation (e.g., during diaper changes and autoinoculation)).²⁹⁶ Contributing to the uncertainty of timing of infection is the delay in presentation of clinical disease. The occurrence of anogenital disease resulting from perinatal infection may be delayed up to 24 months; the development of symptomatic laryngeal papillomatosis (which also arises from perinatal infection) may be delayed up to 5 years.³²⁷ To date, few studies have addressed HPV in sexual abuse. One report attributed sexual abuse as the source of genital warts in 31% to 58% of children 14 years of age and younger.²⁹⁶ Unger et al. found a high prevalence of genital HPV in children with evidence of possible, probable, or definite sexual abuse. However, these authors also found genital HPV in children without evidence of sexual abuse.³⁶³ Further, universal use of HPV vaccine may continue to alter the presence of clinical/microbiologic disease. Nonetheless, with an estimated 702,000 children in the United States suffering from abuse and neglect in 2014, of whom 8.3% were sexually abused,³⁶⁰ the discovery of a mucosal HPV type in a child older than 2 years should prompt investigation into the possibility of child maltreatment.^{147,179}

CLINICAL MANIFESTATIONS

Cutaneous Warts

Common cutaneous skin warts, or verrucae, have variable morphology and may appear at any location on the skin.^{64,320} Common skin warts, or verrucae vulgaris, present as well-demarcated, dome-shaped papules with multiple conical projections (papillomatosis) that give the surface of the wart a rough appearance and texture. Flat warts, or verrucae planae, in contrast, do not have papillomatosis or hyperkeratosis and often occur in clusters. Warts occasionally have a mosaic appearance; such warts occur most commonly on the plantar surface of the feet and spread superficially over the skin. Warts may also be filiform and appear as threadlike warts on the face and neck.⁵³

Common warts generally occur on the hands, especially the dorsum of the fingers, but they also are seen frequently between the fingers. Warts on the hands and feet may occur periungually and on the palms.^{169,301} Plantar warts, also called verrucae plantares, occur most commonly in adolescents and young adults.^{84,168} Plantar warts generally are single lesions and have a highly thickened corneal layer, or hyperkeratosis, with areas of punctate bleeding. Plantar warts may be painful because they typically are found on pressure-bearing points on the plantar surface of the foot. Flat warts are more common findings in young children and occur most frequently on the arms, face, and knees.⁸⁴ Butcher's warts are a form of cutaneous wart seen in meat and poultry handlers who suffer repeated minor trauma to the hands.⁸⁷ Although the clinical appearance of cutaneous warts almost always is diagnostic, the differential diagnosis of warty lesions includes other skin disorders, such as molluscum contagiosum, actinomycosis, blastomycosis, sporotrichosis, leishmaniasis, chronic vegetating pyoderma, atypical mycobacterial infection (e.g.,

swimming pool granuloma), and tuberculosis verrucosa cutis (warty tuberculosis). Giant verrucae or warts also must be differentiated from squamous cell carcinoma.²⁵²

Epidermodysplasia Verruciformis

Epidermodysplasia verruciformis (EV) is a very rare skin disorder initially manifested in infancy or early childhood. It is characterized by the inability to resolve HPV-induced, cutaneous wart-like lesions.²¹⁰ Patients with EV have both nonspecific and HPV-specific defects in cell-mediated immunity, especially T-cell defects; and some patients will have developmental disabilities.^{49,79,139,165,211–213,330,353,368} Although the lesions seen with EV are polymorphic, two clinical types of warts are seen primarily in these patients: flat warts and red or reddish-brown macular plaques. Both the flat warts and plaques appear first on the face, trunk, and extremities. They slowly become confluent and then appear to disseminate. Occasionally, the plaques may be achromatic with pigmented borders and resemble pityriasis versicolor. Histopathologically, EV lesions may appear as an in situ or invasive carcinoma.¹⁶⁵ These EV-related carcinomas generally do not metastasize unless exposed to co-carcinogens, such as radiation.²⁵⁷

Patients with EV may be infected with multiple types of HPVs, including HPV-3 and HPV-10, HPV types associated with flat warts in healthy individuals.^{8,210,250,320} The HPV types most commonly associated with lesions in patients with EV (HPV types 5, 8, 17, and 20) do not usually cause lesions in immunocompetent individuals; however, HPV-8 antibodies have been found in healthy individuals, and HPV-5 DNA and HPV-8 DNA have been detected in refractory warts and skin carcinomas in immunocompromised patients, such as renal allograft recipients.^{85,143,204,272,338} EV-like skin lesions also may be seen in individuals who are immunocompromised as a result of HIV infection, as well as in transplant recipients, those receiving cancer chemotherapy, and other immunosuppressed patients.^{29,31,72}

Infections of Male and Female Genital Tracts

Genital tract HPV is the most common clinical manifestation of mucosal HPV disease and is, in both sexes, the most common viral sexually transmitted infection. Genital tract HPV infection carries high rates of morbidity and mortality to both males and females by its oncogenic potential. However, condylomata acuminata, or genital warts, are the most common genital tract clinical manifestation and rarely develop into dysplastic lesions or invasive carcinoma.^{285,375} Persistent HPV infection is required for the development of neoplasia. Oncogenic HPV types establish persistent infection and express the E7 oncogenes that drive the epithelial cell from G0 into S phase while simultaneously disrupting the apoptotic machinery of epithelial cells. This driving infected cells into S phase and the inhibition of the normal apoptotic response to unscheduled cell division lead to disorganized and uninhibited cell proliferation and disruption of the normal keratinocyte maturation process. HPV persistence is seen before the appearance and even after the regression of cytologic pathology.^{57,310} Early HPV infection manifests as mucosal dysplasia. Grading systems for intraepithelial neoplasias (INs) are similar for the different anatomic areas, increasing in severity going from grade 1 through grade 3, with carcinoma in situ being the most severe. Dysplasia can be further classified into mild (one-third thickness), moderate (two-thirds thickness), or severe (full thickness) based on the extent to which the cervical epithelium is involved with abnormal cells. The majority of mild dysplastic lesions will regress. Moderate and severe dysplasias are considered premalignant lesions. Invasive carcinomas are preceded by a precursor lesion, a carcinoma in situ that morphologically resembles the adjacent invasive squamous carcinoma.^{243,312}

More common than dysplasia and invasive disease in both males and females are condylomata acuminata, or genital warts. Ninety percent of genital warts are caused by HPV types 6 and 11; a small proportion are caused by HPV-16.^{112,190}

Generally, genital warts occur in multiples as flesh-colored, pink, and/or purple-gray papules. Warts, which can also be pedunculated, are covered by an acanthotic squamous epithelium. Giant condylomata acuminata (also known as Buschke-Lowenstein tumors) occur in similar areas as other condylomata but are large, tumor-like lesions that may

cause, albeit rarely, inguinal lymphadenopathy, fistulous tracts, inflammation, hemorrhage, and fibrosis of the surrounding tissue. Buschke-Lowenstein tumors can progress to squamous carcinoma.²⁷⁸

In females, genital warts are found on the vulva and in and around the vagina, the perineum, inner thighs, and anus. Although physically visible and palpable, most lesions are asymptomatic. However, genital warts can cause burning, itching, and pain. Intravaginal and cervicovaginal condylomata, usually in the form of less easily visualized flat warts, are also found and have a higher rate of progression to low- or high-grade dysplastic intraepithelial lesions than external lesions.¹¹³ Anogenital flat warts are most frequently caused by HPV types 6, 11, 16, 18, and 31.¹⁶ During pregnancy, genital warts can increase in size and quantity but often regress after delivery. In males, genital warts can be found on the penis, scrotum, groin and upper thighs, perineum, and anus. Similar to in females, lesions are often asymptomatic but can cause burning, itching, and dyspareunia. Bowenoid papulosis, another clinical manifestation of HPV infection of both the male and female genital tracts—characterized by multiple, large erythematous, maculopapular lesions that can take on a red, purple, or brown color with a smooth, velvety surface—occurs typically in individuals younger than 40 years old. Bowenoid papules may regress spontaneously or may persist as high-grade intraepithelial lesions and are most commonly associated with HPV-16.³⁹

Adolescents can develop genital warts within 1 to 2 months of sexual exposure. Children can have genital and anal warts as a consequence of sexual abuse or from perinatal transmission.^{146,148}

The differential diagnoses of anogenital warts include condylomata lata associated with secondary syphilis, molluscum contagiosum, epithelial papillae, enlarged sebaceous cysts, seborrheic keratosis, lentigo, pigmented nevi, skin tags, hemorrhoids, Crohn disease, and carcinoma.

Female-Specific Disease

Beyond condylomata acuminata, female-specific genital tract disease involves the cervix, vulva, and vagina. Early infection manifests as dysplasia of varying degrees that most often regresses spontaneously but can progress to invasive cancer. The site at which the majority of cervical neoplasias develop (90%) is the squamocolumnar junction. The squamocolumnar junction, located on the face of the cervix in adolescents and later receding into the cervical os in adult women, is the transition zone between the squamous epithelium of the cervix and the columnar epithelium that lines the uterus.³⁹

Cervical epithelial lesions identified by Papanicolaou screening are described using the Bethesda system, which classifies precursor lesions into low-grade squamous intraepithelial lesion (often correlating with the presence of cervical intraepithelial neoplasia [CIN] grade 1 lesions) or moderate/high-grade squamous intraepithelial lesion (HSIL, which often correlates with the presence of CIN grade 2 or 3 lesions).²⁴³ The majority (approximately 60%) of CIN grade 1 lesions regress spontaneously; only 10% progress to CIN grade 3, and only about 1% progress to cervical cancer. In contrast, higher grade lesions have a higher rate of cancer progression. Only one-third of CIN grade 3 lesions are likely to regress, and up to 10% to 12% of untreated cases progress to cervical cancer.²⁵⁶ The risk for progression of CIN grade 3 lesions to cervical cancer increases with age, with 0.5% per year of CIN grade 3 lesions in young women 20 to 24 years old progressing to cervical cancer; this rate of progression increases to up to 10% per year in women 80 years old.^{230,235} HPV types 16, 18, 31, and 45 are the types most strongly associated with cervical cancer. Cervical cancer occurs occasionally due to HPV types 33, 35, 39, 51, 52, 56, 58, 59, and 68 and only rarely due to HPV types 6 and 11.

Using a colposcope, cervical dysplasias and carcinomas appear as pigmented papular or plaque-like lesions and as leukoplakic or, if advanced, larger and/or ulcerated lesions. Cervical dysplasia may or may not be visible to the naked eye. Common clinical characteristics of cervical carcinoma include atypical nonbranching vessels (e.g., corkscrew, comma shape), ulcerations, raised irregular surface, yellow hue to epithelium, and firmness to palpation.

Vulvar intraepithelial neoplasias (VINs) are named to distinguish lesion morphologies. VIN lesions include VIN, usual type; VIN, warty type; VIN, basaloid type; VIN, mixed (warty/basaloid) type; and VIN,

differentiated type. VIN is often asymptomatic and is discovered at the time of gynecologic examination and/or during evaluation for other lesions, such as anogenital warts or cervical dysplasias. VIN lesions are flat or rough elevated papules, are often multicentric, and can occur anywhere on the vulva, including the periurethral and perianal areas. VIN, warty type, is most associated with high-risk HPV, most often HPV type 16. Regression of VIN is common; progression to malignancy most often occurs with the basaloid type. Because of the high frequency of multicentric vulvar disease, patients with suspected VIN should receive a full examination looking for disease of the cervix and vagina. Up to 50% of women with VIN will have an antecedent or concomitant lower genital tract dysplasia, including cervical or vaginal intraepithelial neoplasia.³⁶⁶ As VIN progresses, a more distinct vulvar tumor evolves. The most common characteristics of vulvar carcinoma include red, pink, or white bumps, often with rough or eroded surfaces; persistent, nonhealing ulcer with bleeding; intense vulvar pruritus; burning; and dysuria.^{41,318}

For vaginal disease, the IN classification is employed, using the term *vaginal intraepithelial neoplasia* (VaIN). VaIN is divided into grades 1, 2, and 3 to describe the severity of a lesion. As with cervical and vulvar dysplasia, VaIN is usually asymptomatic, but it can present as abnormal vaginal discharge and/or with spontaneous or postcoital bleeding. VaIN usually affects the posterior upper third of the vagina and presents as single or multicentric lesions³⁸ and cannot be seen without use of a colposcope. VaIN lesions typically have a vascular pattern with punctation and mosaicism. The vascular pattern can become more unusual as lesions become more invasive. Progression of VaIN to vaginal cancer is more unpredictable than other female genital intraepithelial lesions. Fortunately, less than 10% of VaIN lesions progress to invasive cancer.²⁶⁸ Vaginal cancer is rare. In contrast, VaIN is a disease of younger women and is associated with HPV infection. HPV-negative vaginal cancers occur most often in elderly women.

Male-Specific Disease

Male-specific genital tract dysplasia and invasive cancer affect the penis. As in all other genital tract dysplasias, the IN system is used to describe the histologic stage of each lesion (penile intraepithelial lesion [PIN] grades 1, 2, and 3 and penile carcinoma in situ). Penile dysplasia and invasive disease present most often as a lump or nodule and sometimes as an ulcerative or erythematous lesion. Penile dysplasia can also present as phimosis, penile pain, and bleeding along with a foul-smelling discharge. Because of social stigma and psychological stress surrounding penile pathology, clinical presentation is often late.^{50,86} Squamous cell carcinoma is the most common type of neoplasia of the penis, with several different types described: classic, basaloid, verrucous, sarcomatoid, and adenosquamous.³³² About half of penile carcinomas are HPV associated, most often the warty-basaloid type. HPV-16 and less so HPV-18 are most commonly associated with HPV-associated PIN and invasive penile cancer. Invasive cancer is localized to the glans most commonly, then the prepuce, with the least amount of disease seen on the coronal sulcus and shaft. If penile carcinoma in situ involves the glans, it is also known as erythroplasia of Queyrat; if disease involves the shaft, it is also known as Bowen disease. In Bowen disease, inguinal lymph node involvement is common.

Recurrent Respiratory Papillomatosis

RRP is a rare, potentially life-threatening condition caused by HPV types 6 and 11.^{91,119,155,183,370} Worldwide, RRP probably is the most common tumor of the larynx in children, with an incidence of 0.1 to 2.8 per 100,000 observed.^{342,364} In the United States, the estimated incidence of RRP in children is 0.6 to 4.3 per 100,000 and up to 1.8 per 100,000 in adults.⁸⁸ RRP is newly diagnosed in an estimated 1500 patients each year.^{88,236,364} The disease may be seen in both children and adults. Approximately two-thirds of cases of RRP are seen in children; the disease is then referred to as juvenile-onset recurrent respiratory papillomatosis (JORRP).⁷⁶ In children, approximately a fourth of the cases will be present before age 1 year; half are present by age 5 years, and the other half by age 11 years. Adult-onset RRP is most often first seen in patients between 20 and 40 years of age, but occasionally RRP may be seen in adolescents.^{119,237,320}

Infants and children with JORRP most likely acquire HPV infection perinatally during passage through an HPV-infected birth canal. Thirty percent to 60% of mothers of children with JORRP have a history of genital warts, compared with less than 5% of mothers of children who do not have JORRP; children with JORRP rarely are born by cesarean section.^{28,265,280,321} Risk factors for JORRP include vaginal delivery, being firstborn, and maternal age younger than 20 years.³²² HPV types 6 and 11, the HPV types most commonly associated with genital warts seen in women, also underlie most cases of JORRP.^{37,107,320} Although HPV DNA has been detected in the oropharynx of infants born to mothers with genital HPV infection,³²⁰ RRP develops in only a small proportion of infants born to mothers with genital warts or subclinical HPV infection.²⁹³ The presence of HPV DNA in human breast milk renders this mode of transmission also a possibility for some infants.³⁰⁶ The mode of transmission of HPV types 6 and 11 in adult-onset RRP is unknown.

The most common initial symptom of RRP and JORRP is hoarseness or a change in voice. Infants and toddlers may have a hoarse cry, stridor, airway obstruction, respiratory distress, or difficulty in phonation. They also may have a crouplike illness. The most common site for RRP and JORRP is the true vocal cord of the larynx. Supraglottic and subglottic extension of the lesions also may occur. In addition, the disease may involve the trachea, bronchi, palate, nasopharynx, paranasal sinuses, and lungs. When the lungs are involved, pulmonary nodules, atelectasis, and secondary bacterial pneumonia may occur (Fig. 155.1). The disease also may produce permanent lung damage with bronchiectasis and cavitations (Fig. 155.2). In 2% to 3% of patients, progression to invasive squamous papillomatosis and even malignant transformation to squamous cell carcinoma will occur, with invasion of the soft tissues of the neck, esophagus, and lung parenchyma; such an exceptionally aggressive disease course may occur in association with infection by HPV type 16 (Fig. 155.3).^{331,383} The incidence of progression to squamous carcinoma increases to 14% in patients who received the radiation therapy that was commonly used previously to treat RRP.^{78,133,214,313} Smoking and severe recurrent disease are also risk factors for development of malignant transformation in adolescents and adults. Clinical courses of RRP and JORRP are highly variable and characterized by common and unpredictable remissions and exacerbations, even despite apparently successful removal of the lesions. Longitudinal studies of JORRP show that infection with HPV type 11 and age younger than 3 years at initial diagnosis are associated with more aggressive tracheal disease requiring frequent surgical debulking.^{78,261,383} Sudden and unexpected death may also occur from airway obstruction if the lesions obstruct the laryngeal lumen.³³³

The mainstay treatment of RRP is surgical debulking, with the goal of reducing tumor burden, decreasing spread of disease, maintaining airway patency, and prolonging time between surgical procedures. Because of the recurrent nature of disease, adjuvant pharmacotherapy is used in some cases. Use of interferon alpha has shown mixed results, with remission demonstrated in some patients and no benefit to others.³⁷⁰ Interferon alpha binds cell receptors and produces antiviral, antiproliferative, and immunomodulatory effects. Cidofovir has been used, mostly intralesionally, with a few additional reports of inhaled delivery.³⁷⁰ Studies with intralesion administration have reported complete resolution in up to 57% of patients and partial resolution in 35%.¹²³ Both interferon alpha and cidofovir have significant toxicities that need to be taken into account when considering their use. Other pharmacotherapies are being investigated, including indole 3 carbinol, a substance from cruciferous vegetables that has been found to decrease papilloma growth through alterations of estrogen metabolism. Also being investigated is a therapeutic vaccine, HSPE7 (a recombinant protein combining heat shock protein 65 of *Mycobacterium bovis* with E7 protein of HPV-16), which, when administered subcutaneously as an adjuvant to surgery, has shown a decrease in the number and frequency of papilloma debulking surgeries required.³⁷⁰ Intralesional mumps vaccine has shown prolonged remission in children³⁷⁰ and continues to be studied. COX-2 inhibitors are being tested.³⁸⁵ Bevacizumab (a vascular endothelial growth factor inhibitor) is also being investigated as adjunctive therapy.³⁸⁵ Last, initial studies have shown an added benefit to antireflux therapy.³⁷⁰

FIG. 155.1 Chest radiograph of a 6-year-old girl with severe, recurrent, and progressive respiratory papillomatosis since 1 year of age.

FIG. 155.2 Computed tomographic chest scan of a 6-year-old girl with severe, recurrent, and progressive respiratory papillomatosis shows pulmonary nodules, bronchiectasis, and cavitations.

FIG. 155.3 Lung biopsy tissue from a 6-year-old girl with severe, progressive, recurrent respiratory papillomatosis. This specimen demonstrates invasive squamous papillomatosis. The squamous cells are growing along preformed pulmonary structures, but no evidence of malignancy is apparent at this time because of the absence of invasion of lung tissue (hematoxylin and eosin stain, $\times 50$ original magnification, light microscopy). (Courtesy Dr. Claire Langston, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)

Upper Respiratory Tract Papillomas

Nasal papillomas or warts are rare tumors that may develop at any age, including childhood, and may occur as solitary lesions or in combination with papillomas elsewhere in the respiratory tract.^{41,289} Histologically, they usually resemble the laryngeal papillomas seen in RRP. They most commonly are caused by HPV types 6 and 11, although HPV types 16, 57, and 57b also have been detected in nasal papillomas. Cocaine snorting is one risk factor for the development of nasal papillomas.^{316,339} Papillomas also may involve the paranasal sinuses.^{42,289}

Conjunctival papillomas occur in all age groups but are exceedingly rare (Fig. 155.4). Conjunctival papillomas may be asymptomatic initially but with increasing size can cause a constant foreign body sensation or chronic conjunctivitis. When large, they appear as pink mulberry- or cauliflower-like growths that may cause pain or interfere with lid closure. In most children and some adults, conjunctival papillomas appear to be caused by HPV types 6 and 11, which characteristically infect the genital tract and, therefore, similar to RRP, may be transmitted during birth.^{191,223} HPV type 16, another HPV that commonly infects the genital tract, also has been associated with conjunctival and lacrimal sac carcinoma in adults.^{207,222}

Gastrointestinal Disease

Oropharyngeal Cancer

HPV-associated oropharyngeal cancers typically occur within the base of the tongue, tonsils, soft palate, and walls of the pharynx. As previously mentioned, although head and neck cancer risk has been closely linked to increasing age and alcohol and tobacco use, persistent oral HPV infection is now increasingly recognized as a leading cause of oral and oropharyngeal cancers. An association with having a higher number of oral sexual partners (more than five) has been demonstrated in individuals with HPV-positive exfoliative cells within their oropharynx; thus, oral sexual behaviors translate into risk for oropharyngeal disease and cancer. Individuals at risk for persistent oral HPV infection include smokers, individuals of older age, those with low CD4 count, and those on HAART for a long period of time.^{47,75}

HPV-associated oral and oropharyngeal cancers are most commonly associated with HPV type 16, which accounts for over 90% of HPV-associated disease.⁴³ This rising HPV-associated disease prevalence is most striking in the United States and less so in Europe and other areas.⁶⁴ Not only have HPV-associated oropharyngeal cancers been increasing in incidence overall, but, anatomically, this increase is seen particularly within the palatine and lingual tonsils.^{80,153} HPV targets the specialized

FIG. 155.4 Focal epithelial hyperplasia of the oral gingiva and mucosa (Heck disease). Patient was a 3-year-old Hispanic boy with a history of orthotopic liver transplantation and mild acute organ rejection who had an extensive eruption of painless, rounded, soft nodules present on the tongue, buccal mucosa, and gingivae. (Courtesy Dr. Federico Laham, Department of Pediatrics, Baylor College of Medicine and Texas Children's Hospital, Houston, TX.)

reticulated epithelium lining the tonsillar crypts.²²¹ HPV-associated cancer most commonly occurs next within the soft palate and Waldeyer's ring (the uninterrupted ring of lymphoid tissue including the tubal, pharyngeal, palatine, and lingual tonsil). HPV-associated malignancy can also occur in other head and neck regions.^{185,246,346,355,369}

Cancer of the oral cavity and oropharynx often presents with delayed clinical signs. Clinical signs and symptoms can include persistent odynophagia, dysphagia, palpable or visible lump in throat or mouth, changes in voice, increased cough, and otalgia.⁹² Most often, individuals have a nonhealing ulcer or sore.^{15,295,356} Given the increasing prevalence of HPV-associated head and neck cancers, an adult with a later neck mass must be assumed to have an HPV-associated malignancy until proven otherwise.¹²⁸

Interestingly, individuals with HPV-associated head and neck cancer have better clinical outcomes after therapy compared with those with HPV-negative head and neck cancers. This is likely due to a host of factors, including greater local-regional control of HPV-positive lesions and a higher intrinsic sensitivity of HPV-positive lesions to radiation and cisplatin therapies.¹⁰ HPV-associated cancers are also found to have less cancer recurrence.²⁵⁴ It is possible that identification of HPV in the oral cavity could serve as a biomarker for monitoring of early disease, disease progression and regression, tumor staging, and continued post-therapeutic surveillance.²²¹

Anal Cancer

While anal cancers remain uncommon, the incidence of anal cancers is increasing at approximately 2% per year.³¹⁹ Importantly, there are groups with increased incidence of anal disease and cancer, particularly women with HPV-associated cervical disease, men who have sex with men, solid-organ transplant recipients, and individuals with concurrent HIV infection.^{73,114,263}

Like the cervix, the anus has a squamocolumnar junction, and, like the cervix, it is this squamocolumnar junction that is most susceptible to HPV infection and is most prone to the development of dysplasia. HPV types 16 and 18 (and 31 less so) are most commonly associated with anal cancer. Even though anal warts are largely associated with HPV types 6 and 11, anal warts are still associated with invasive anal disease, perhaps because of their association with other sexual risk behaviors and predisposition to other, more oncogenic HPV types.^{116,142,187,247,260}

Similar to all other intraepithelial lesions and cancers, the IN grading system is used, applying the term *anal intraepithelial lesion* (AIN) and a number (i.e., AIN 1 to 3) for classifying the severity of anal disease. Similar to other grade 1 lesions at other sites, AIN 1 is not considered a precancerous lesion. Higher grade lesions (AIN 2 or 3) can progress to invasive cancer.⁶⁶ AIN lesions are often warty and white but can be gray and/or pigmented. At the anal verge, lesions are often associated with epithelial stalks, each containing a single-looped capillary. Anal tags can have AIN and are often mistaken as hemorrhoids.

The age of anal cancer diagnosis in females is most often in the mid to late 60s. Women with related anogenital disease and intraepithelial neoplasia have a higher risk for developing anal cancer. Approximately 30% of women with VIN have involvement of the anal canal with AIN.²⁶⁰ The average age at anal cancer diagnosis in males is the mid to late 50s.²⁶⁰ In men who have sex with men, in particular, there is a high incidence and prevalence of anal disease and cancer found in both HIV-positive and HIV-negative individuals, with age-related prevalence approximately 60% across all age groups.¹⁴² HIV-positive men who have sex with men are at highest risk for HPV infection and its sequelae.^{150,362} Interestingly, despite the introduction of HAART, the incidence of HPV-associated anal disease and cancer in the HIV-positive men who have sex with men has continued to increase. It is postulated that because individuals are living longer on HAART, there is more time for slowly progressing AIN to develop into invasive disease, all the while with unchanged levels of surveillance for anal disease in this surviving population.^{99,266,276}

LABORATORY DIAGNOSIS

Although most HPV infections are asymptomatic, the typical appearance of verrucae vulgaris on the skin and condylomata acuminata in the

anogenital area in otherwise healthy individuals usually is sufficient to establish the clinical diagnosis of HPV infection. Laboratory confirmation of HPV-associated lesions may be necessary for unusual manifestations in healthy individuals, for immunocompromised patients, and for patients with suspected malignant lesions. Because HPVs cannot be grown in cell culture monolayers, a variety of molecular methods, used alone or in combination, are used in research and clinical settings.³⁹² Cytologic and histologic approaches also are helpful in diagnosing HPV-associated cancers.

Electron Microscopy

Although not used clinically, electron microscopy can be used to detect virions with typical papillomavirus morphology in cutaneous warts. Such virions are difficult to detect in tissue from patients with RRP, JORRP, genital warts, or in histologically diagnosed cancers.

Cell Culture

HPVs have not been propagated in cell culture monolayer. Therefore, the routine viral cultures available in most diagnostic virology laboratories will not detect the presence of HPVs.

Serology

HPV serologies are not used clinically and are not available in most diagnostic laboratories. Serologic methods have been used extensively in recent clinical trials of HPV vaccines; however, in natural infection, only 60% of women with proven genital HPV infections mount a detectable type-specific IgG response.*

Cytology

Since the 1960s, the Papanicolaou technique for obtaining and staining exfoliated cervical cells (i.e., the Pap smear) has been a procedure used widely as a screening method for detection of dysplastic and malignant cervical epithelial cells. Despite its relative insensitivity, the widespread and consistent use of the Pap smear has reduced dramatically the incidence of invasive squamous cell carcinoma of the cervix in nations with robust screening programs. Although screening guidelines vary by country and evolve constantly, cervical cytology screening is generally recommended at 1- to 3-year intervals for sexually active women. Current cervical cytology screening recommendations from the American College of Obstetrics and Gynecology are as follows:

- Screening should occur every 3 years between ages 21 and 29 years. HPV testing is not recommended.
- Women aged 30 to 65 years should have a Pap test and an HPV test (co-testing) every 5 years (preferred). It also is acceptable to have a Pap test alone every 3 years.
- Women who have a history of cervical cancer, are infected with HIV, have a weakened immune system, or who were exposed to diethylstilbestrol before birth may require more frequent screening and should not follow these routine guidelines.
- Having an HPV vaccination does not change screening recommendations. Women who have been vaccinated against HPV still need to follow the screening recommendations for their age group.
- Sexually active adolescents should be counseled and tested for sexually transmitted infections and counseled about safe sexual practices and about contraception.¹⁶⁴

The operator characteristics of cervical Pap smear screening are dependent on the expertise of the physician who obtains the specimen and of the cytologist who performs the cytologic analysis.²³³ Because most cervical neoplasias arise at the junction of the squamous and columnar epithelium of the cervix (transformation zone), care must be taken to obtain cells from this region. Substantial interobserver variability also occurs among cytologists who read Pap smears.²⁵

The cytologic abnormalities identified on Pap smears reflect the cytopathic effects of HPV infection in cervical epithelial cells. The cytologic abnormality characteristic of HPV infection is koilocytosis (derived from the Greek word *koilos*, which means “hollow” or “cavity”). Koilocytotic cells display fat, swollen, wrinkled, or raisin-like nuclei surrounded by a halo, giving infected cells an owl’s eye–like appearance.

Other cytologic abnormalities—including dyskeratosis, parakeratosis, and hyperkeratosis—may occur but are considered secondary or nonspecific. In women screened by Pap smears consistently, the prevalence of cytologic abnormalities has been estimated at 2% to 3%.^{158,314} Reflecting the spontaneous resolution rate of HPV infections, most cytologic abnormalities detected on Pap smears resolve spontaneously in 3 to 6 months. Nonetheless, cytologic abnormalities evolve in some patients, reflecting progression from infection through dysplasia to cervical squamous cell carcinoma. As HPV infection progresses to disease, the koilocytosis typically diminishes and the cervical epithelial cells begin to display dysplastic changes and nuclear abnormalities. While several Pap smear grading systems have been developed, the Bethesda system is used in the United States.¹ In the Bethesda system, the cytologic abnormalities seen on Pap smears are graded into four categories: (1) atypical squamous cells (this category is subdivided into atypical squamous cells of uncertain significance, ASC-US, and atypical squamous cells—cannot exclude high-grade squamous intraepithelial lesion, ASC-H); (2) low-grade squamous intraepithelial lesion; (3) HSIL; and (4) squamous cell carcinoma.^{243,312}

Colposcopy

Evaluation by cervical colposcopy typically follows for women with abnormal Pap smears or external anogenital warts. Gynecologists, urologists, and family practitioners, as well as pediatricians who are specialists in adolescent medicine, usually perform the procedure. Briefly, the cervix, vulva, and anus in females or the urethral meatus, penis, scrotum, and anus in males are visualized under magnification with a colposcope to identify lesions, with special attention paid to their topography, the presence of abnormal whitening, and their vascular architecture. The area then is soaked in acetowhite (3–5% acetic acid) and reexamined for the presence of previously undetected lesions that appear as whitened plaques. Although whitening with acetowhite treatment is useful for detection of lesions, whitening after application of acetic acid is not specific for HPV infection or disease. Therefore, biopsy is required for definitive diagnosis. Tissue biopsy specimens are sent for histologic examination and for detection of HPV DNA by molecular techniques. Anal colposcopy, referred to as anoscopy, is similar to cervical colposcopy and is used to screen men and women at high risk for anal HPV infection.

Histology

HPV infection most often occurs in histologically normal tissue and is detectable only by molecular methods that detect viral DNA. Benign and asymptomatic HPV infection also may cause koilocytosis. Condylomata acuminata lesions display koilocytosis and other histopathologic characteristics of active HPV infection, such as hyperkeratosis, parakeratosis, acanthosis, and lengthening of the rete pegs. Atypical features, including mitotic figures above the basal layer, dysplastic cells, and single-cell keratinization, indicate higher grades of dysplasia. Precancerous and cancerous lesions of the cervix, vulva, vagina, penis, and anus also may be graded as low-grade or high-grade squamous intraepithelial lesions and invasive squamous cell carcinoma. In like manner, HPV-associated oral and oropharyngeal lesions are graded according to cellular atypia and invasion.

Molecular Methods That Detect Human Papillomavirus DNA

A nonradioactive, chemiluminescent liquid hybridization assay (hybrid capture assay) is commercially available and detects as many as 14 HPV types divided into high-risk (types 16, 18, 31, 33, 35, 45, 51, 52, 56) and low-risk (types 6, 11, 42, 43, 44) groups on the basis of association with cervical cancer.^{209,211,311} This DNA hybrid capture assay is relatively rapid and simple to perform and is used typically as a reflex test to detect and classify (high-risk or low-risk) HPV DNA in abnormal cervical cytology specimens. Although this DNA hybridization/amplification method is in widespread clinical use, the laboratory and clinical use of other HPV DNA detection methods—including dot-blot, slot-blot, Southern blot, and in situ hybridization—have largely been supplanted by PCR.* Commercially available PCR-based assays capable of identifying

*References 14, 35, 54, 117, 118, 143, 156, 160, 194, 213, 297, 337, 389.

*References 58, 145, 152, 216, 249, 251, 267, 348, 374, 376, 390, 391.

and distinguishing 37 high- and low-risk mucosal HPV types are used in clinical trials but are not yet approved for diagnostic use in the United States.

More recently, a variety of PCR-based HPV detection methods have become available commercially (e.g., see <http://www.mayomedicallaboratories.com/test-catalog/Clinical+and+Interpretive/62599>). These tests are designed to detect broad arrays of oncogenic HPV types, and provide genotype identification. This is a rapidly evolving area of molecular diagnostics. While these methods are valuable for epidemiologic studies of HPV, and have proven very useful in vaccine clinical trials, how type-specific identification of HPVs assists in clinical management remains controversial.

In Situ Hybridization

In situ tissue DNA hybridization assays are performed directly on fresh or fixed tissue sections or on cytologic specimens. In situ assays offer the unique advantage of allowing the examiner to correlate histopathologic abnormalities with the location of HPV DNA. In situ assays may be performed with radioactive or enzyme-labeled probes. Commercial reagents and kits are available. Given the greater sensitivity and ease of detection, immunohistochemical detection of p16 antigen appears to be a sensitive and specific surrogate for tumor HPV positivity.^{35,82,328}

TREATMENT

In healthy individuals, most HPV-associated lesions will regress spontaneously in 1 to 2 years. Treatment may be desirable if the lesions are large, multiple, or recurrent; if they cause pain or discomfort; or if they are undesirable cosmetically. Treatment is required if the lesions are life threatening, such as laryngeal papillomas that obstruct the airway, or lead to cervical cancer. A variety of treatment strategies are available, but none produces a universally effective or permanent cure. Rather, currently available approaches seek reduction of the clinically apparent lesion, and most require repetitive application. Clinically significant HPV-associated lesions also usually require care by a specialist. For example, a dermatologist should be consulted to assist in the management of a patient with severe recalcitrant cutaneous warts, a gynecologist for patients with cervical dysplasia, an oncologist for patients with cervical cancer, a colorectal surgeon for patients with anal dysplasia or carcinoma, an ophthalmologist for patients with conjunctival papillomas, and an otolaryngologist and pulmonologist for children and adults with severe RRP. The role of the infectious disease specialist in the management of HPV-associated disease is evolving and is principally to ensure that high-risk patients under their care (i.e., patients who are immunocompromised, posttransplant, HIV infected, or have had multiple sexually transmitted infections) are referred regularly for screening and treatment. Infectious disease physicians will become more directly involved in the care of HPV-associated diseases when HPV-specific antiviral chemotherapy becomes available for clinical trial and eventually for routine clinical use in patients.

Surgical techniques used to treat papillomas include traditional local excision, cryotherapy with liquid nitrogen or dry ice, electrocautery and curettage, and ultrasonication.^{17,33,34,109,170,219,329} Newer ablative surgical techniques that use carbon dioxide laser vaporization and flash-lamp pulsed-dye laser therapy allow more precise and complete removal of visible papillomas and are becoming widely used to treat genital and laryngeal papillomas.^{108,287,343} Surgical excision by knife remains the mainstay of HPV treatment, however, because excision provides tissue for a histopathologic diagnosis, as well as removal or debulking of large lesions. Ablation by cryotherapy with liquid nitrogen, electrocautery, or laser vaporization may be used to remove small, single, or multiple lesions or may be performed in combination with surgery for large or difficult lesions.^{226,308,309} These surgical therapies also may release viral antigens, evoking a local and systemic immunologic response that may assist in eradicating the lesions. Disadvantages of these physical methods of wart and papilloma removal include pain, scarring, and disfigurement. These methods also are relatively invasive and impractical for patients with disseminated disease. Furthermore, recurrent treatments usually are necessary. In addition, laser vapors contain HPV DNA and may be a vehicle for spreading the infection in the patient or to the

treating physician or surgeon; thus, the vapors or smoke plume should be contained.^{129,307} Recurrence of lesions after treatment occurs commonly and most likely is due to the presence of HPV DNA sequences in clinically and histologically normal epithelium adjacent to and beyond the treatment area.¹¹⁰ The mainstay of treatment for RRP and JORRP is repeated surgical debulking of obstructing papillomas augmented by immunomodulators and antiviral therapies.^{141,155} Surgical rates tend to decrease over time in many patients; however, those patients infected with HPV type 11 may eventually require more frequent, more extensive, and more prolonged surgical procedures.^{281,384}

Warts and papillomas also may be disrupted physically and removed by using chemical ablatives applied topically to the lesion. Simple organic acids such as bichloroacetic acid, trichloroacetic acid, or salicylic acid applied twice daily for several days have shown some success in the localized treatment of skin and genital warts.¹²⁰ They are caustic substances that produce a white slough that peels off, and they can be applied weekly until the lesion is destroyed.¹²⁰ Antimitotic agents such as podophyllin or the newer preparation podophyllotoxin can be applied twice daily for several weeks. Antimetabolites such as bleomycin, cantharidin, and 5-fluorouracil also have shown efficacy when administered locally once or twice a week because they inhibit the cellular proliferation induced by HPV infection.^{182,274} These topical chemicals are easily applied to skin and genital warts but may cause local pain, redness, swelling, irritation, blisters, and scarring.¹⁸² Moreover, antimetabolites are not virus specific, and recurrences are common. Antimetabolites are impractical for extensive lesions and may be toxic if used in certain circumstances. For example, they may damage the cornea if used to treat conjunctival papillomas. Antimetabolites should not be used on pregnant women.²²⁶ The systemically administered antitumor agent methotrexate also has been administered to individual patients with disseminated HPV disease, with variable success.

Immunomodulation is another treatment strategy for HPV-associated disease. A systemic immunologic response probably is responsible for the spontaneous regression frequently observed in cutaneous and mucosal warts. Therefore, stimulation of the immune system with immunomodulators also may produce remission in patients with HPV-associated disease. Interferons have antiviral, antiproliferative, and immunomodulating properties. Decades of clinical experience have accrued in treating HPV-associated disease with interferon administered topically, intralesionally, or systemically by subcutaneous injection. Both lymphoblastoid and fibroblast interferon have been used with some success to treat patients with genital warts and respiratory papillomatosis topically, locally, and systemically.^{103,115,122,155,286,315,320} However, interferon- γ has not been shown to be beneficial. Both recombinant and natural-source interferon- α preparations have been demonstrated in placebo-controlled trials to be effective and are approved by the US Food and Drug Administration (FDA) for the intralesional treatment of genital warts.^{103,104} A 25- to 30-gauge needle is used to inject approximately 0.1 mL (1×10^6 units) at the base of up to five warts at a time for a total dose of 5×10^6 units at each visit. This dose is repeated two to three times weekly for 3 weeks. Maximal effect usually is seen within 4 to 8 weeks. Repeat injections may be given if the warts are persistent or recurrent. Interferon therapy also may be effective if used alone or in combination with laser surgery to treat patients with RRP.^{152,156,195,205} Fever, headache, chills, and myalgia frequently occur with local and systemic interferon treatment. Severe and persistent fatigue, nausea, and leukopenia are other fairly common adverse reactions, especially with systemically administered interferon. Systemic natural leukocyte interferon also causes regression of warts and reduction of the virus load in tissues in patients with EV.⁹ Cimetidine, an immunomodulator that alters lymphocyte function, has been used in an attempt to treat children with recalcitrant cutaneous warts.²⁵³

Topical immunotherapeutic agents provide alternative treatment options for HPV-associated disease in some patients.^{130,132,178,227,320} Imiquimod, also known as imidazoquinoline, is a first-generation member of a class of immune response modifiers approved for topical treatment of genital and perianal warts.^{130,132,178,227} Imiquimod is a synthetic compound that is a topically active Toll-like receptor-7 agonist. It activates innate immune cells to produce interferon- α and other cytokines

to enhance antigen presentation and promote antigen-specific T-helper type 1 cell-mediated immune responses. Imiquimod is marketed as a 5% cream that is applied to lesions and appears to be effective in some patients. Resiquimod and other related second-generation imidazoquinoline analogs also are in clinical development.

Retinoids and retinoic acid, which are analogs of vitamin A, can regulate the growth and differentiation of malignant, premalignant, and even normal cells.^{5,288} Clinically, retinoids have a documented effect against squamous cell carcinoma.^{198,199} For these reasons, anecdotal reports and small series of patients have emerged in which retinoic acid was used to treat HPV-associated disease, especially RRP. In these reports, retinoids were used with varying success, primarily as adjuvant agents with surgical therapy, to treat adult patients with severe refractory RRP.^{20,101} The combination of interferon and retinoic acid has been shown to be synergistic against breast cancer cells in vitro and potentially may be useful in refractory cases of RRP.²²⁰

Unique aspects of HPV infection and disease render designing specific antiviral therapies a challenge. For example, HPV disease usually is focal, viral replication is tied intricately to the host cell's life cycle, and HPV has great diversity with more than 70 genotypes. The inability to grow HPVs readily in cell culture also hampers our ability to study the antiviral properties and cellular toxicities of candidate compounds. Molecular assays that isolate individual viral functions, therefore, have been used to evaluate the ability of antiviral compounds to inhibit each individual step in the virus life cycle. Furthermore, animal models for HPV-associated disease are lacking. Despite these challenges, the in vitro antiviral activity and clinical efficacy of a variety of compounds have been studied. Ribavirin, a purine nucleoside analog with a broad antiviral spectrum, has been used in clinical trials for the treatment of laryngeal papillomatosis.²²⁴ As noted before, cidofovir, an antiviral compound effective against serious disease caused by cytomegalovirus, also appears to have activity against HPVs, and possible clinical benefit for certain HPV-associated disease has been shown. For example, repeated intralesional administration of cidofovir directly into the site of papillomas and also submucosally at the sites of resected papillomas is associated with partial or complete regression of lesions, improvement of voice quality and airway status, and decreased need for repeat surgery. Published studies report a wide variety of intralesional doses (2–57 mg of a 5 mg/mL cidofovir concentration solution), frequency of injections (every 2–8 weeks), and duration of treatment (4 months to 4 years). Rarely, cidofovir has been administered intravenously in patients with refractory, disseminated papillomatosis.¹⁵⁵ The greatest benefits have most often been documented after the fourth series of injections, and benefit appears to plateau after the eighth series of injections in most patients.^{67,70,96,125,151,215,323,324} However, because most published reports are single-center, uncontrolled case series with relatively small numbers of patients, controlled, multicenter trials with larger numbers of patients are necessary to accurately determine the benefits of cidofovir therapy and the optimal dose, frequency, and duration of therapy for RRP and JORRP.³⁵⁴

PREVENTION

Secondary prevention by cytologic screening remains an essential component of cancer prevention programs. Historically, screening practices for HPV-associated diseases have focused on cervical cytology. Today, most cases of invasive cervical cancer are preventable with regular screening for precancerous lesions (e.g., by Pap smear) and close follow-up of abnormal results. As mentioned earlier, cervical cytology screening is a continuously evolving process, with the largest changes to the most recent recommendations advocating for screening starting at age 21 years.^{3,13,164}

Data analyses from the National Health Interview Survey find overall cervical cancer screening rates of just over 80%, with lower rates among Asian, American Indian/Alaska Native, Hispanic, and foreign-born women. Higher rates of cervical cancer seen among black and Hispanic women are likely multifactorial but are, in large part, related to reduced access to screening and/or follow-up care. In these same disproportionately affected ethnic groups, the disparity of HPV and cancer rates will likely continue to grow if these groups are undervaccinated.^{99,266}

Anal cancer shares many similarities with cervical cancer. As such, more aggressive screening (similar to cervical cancer screening) is needed to decrease its incidence.²⁶¹ Anal cytology serves as the primary screen and is described according to the Bethesda system for cervical cytology (normal, atypical squamous cells of undetermined significance, low-grade squamous intraepithelial lesion, HSIL, and atypical squamous cells, cannot rule out HSIL).¹²¹ Individuals with anal cytologic abnormalities should be referred for high-resolution anoscopy (HRA) with biopsy. HRA is similar to cervical colposcopy and can be done in the ambulatory setting. The utility of HRA is highly dependent on the expertise and proficiency of the operator. An anoscope is inserted and a colposcope is used for visualization of the squamocolumnar junction, the distal anal canal, and the anal margin. Acetic acid and Lugol's iodine are applied to the mucosa and biopsies are obtained from abnormal sites.^{121,261} HRA, similarly to colposcopy, can be used in conjunction with ablative therapies for treatment of HPV-associated anal dysplasias. Anal histology is graded based on mucosal dysplasia: mild dysplasia is graded as anal intraepithelial neoplasia I (AIN I; low-grade dysplasia) and moderate dysplasia is graded as anal intraepithelial neoplasia II or III (AIN II or III; high-grade dysplasia).¹²¹

Quadrivalent HPV Vaccine

In June 2006, the FDA approved the first vaccine to prevent HPV-associated dysplasias and malignancies. This quadrivalent recombinant vaccine against serotypes 6, 11, 16, and 18, given as a series of three 0.5-mL intramuscular injections at 0, 2, and 6 months, is now approved for females and males ages 9 through 26 years old. The vaccine, prepared using purified viruslike particles (VLPs) of the capsid (L1) protein of HPV types 6, 11, 16, and 18, stimulates humoral and cellular immune responses to HPV L1 capsid proteins.

The quadrivalent HPV vaccine is indicated for prevention of the following HPV-associated diseases *due to vaccine types* in females:

- Cervical, vulvar, vaginal, and anal cancer
- Genital warts
- CIN grades 1/2/3 and cervical adenocarcinoma in situ (AIS)
- VIN grades 2/3
- VaIN grades 2/3
- AIN grades 1/2/3

The quadrivalent HPV vaccine is indicated for the prevention of the following HPV-associated diseases *due to vaccine types* in males:

- Anal cancer
- Genital warts
- AIN grades 1/2/3

Quadrivalent HPV Vaccine Efficacy

Quadrivalent HPV vaccine efficacy has been assessed in six double-blinded, randomized controlled trials, together evaluating over 28,000 males and females ages 16 through 26 years. Among these trials, the FUTURE I/II trials of vaccine efficacy and safety provided most of the efficacy and safety data submitted to support vaccine licensure.^{14,117,118,174,217}

Females. Primary analysis of efficacy regarding HPV types 6, 11, 16, and 18 were conducted in the per protocol efficacy (PPE) population, which consisted of women ages 16 through 26 years, who were HPV naïve to the relevant strains 1 month before the first dose, remained negative until 1 month after the third dose, received all three doses within 1 year, and had no protocol violations. Detection of CIN grades 2/3, AIS, VIN grades 2/3, and VaIN grades 2/3 were the efficacy endpoints to assess prevention of cervical, vulvar, and vaginal cancer. Presence of external genital lesions was the efficacy endpoint to assess prevention of genital warts. Anal disease and anal cancer were not endpoints in the female studies.

In combined analysis from all clinical trials, efficacy was 98%, 100%, and 100% against HPV type 16 or type 18–related CIN grades 2/3 + AIS, VIN grades 2/3, and VaIN grades 2/3, respectively. By HPV type, vaccine prevented 98% of HPV type 16–related lesions and 100% of HPV type 18–related lesions. The vaccine prevented 99% of anogenital condyloma infections related to HPV types 6, 11, 16, and 18.^{46,48}

Secondary analysis approximated the impact on the general population of young American females. This intention-to-treat analysis looked at vaccine efficacy in those receiving at least one dose of the vaccine in

both HPV-naïve females and females regardless of HPV status. Females who were HPV naïve at day 1 were found to have reduction of genital warts, CIN grades 2/3 + AIS, and VIN + VaIN grades 2/3 by 83%, 43%, and 77%, respectively. Females regardless of HPV status were found to have reduction of genital warts, CIN grades 2/3 + AIS, and VIN + VaIN grades 2/3 by 63%, 18%, and 51%, respectively.^{14,22,117,118,126,362}

Males. To assess the efficacy of the quadrivalent vaccine for the prevention of genital warts in males, primary analysis of efficacy against disease due to HPV types 6, 11, 16, and 18 was conducted in the per protocol efficacy population, which consisted of males ages 16 through 26 years who were HPV naïve to the relevant strains 1 month before the first dose, remained negative until 1 month after the third dose, received all three doses within 1 year, and had no protocol violations. Presence of external genital warts and penile/perineal/perianal intraepithelial neoplasia (PIN) grades 1/2/3 were the efficacy endpoints to assess prevention of penile/perineal/perianal cancers. Vaccine efficacy for prevention of anal disease was assessed in a substudy population of men who have sex with men derived from the larger per protocol efficacy male population.

In combined analyses from all clinical trials, quadrivalent vaccine efficacy was 100% and 78% for prevention of HPV types 6, 11, 16, and 18-related PIN grades 1/2/3 and AIN grades 1/2/3, respectively. The quadrivalent vaccine prevented 90% of anogenital condylomas related to HPV types 6, 11, 16, and 18.¹³⁸

Secondary analysis approximated the impact on the general population of young American males. This intention-to-treat analysis assessed vaccine efficacy in men receiving at least one dose of the vaccine in both HPV-naïve males and males regardless of HPV status. Males who were HPV naïve at day 1 were found to have reduction of external genital lesions, genital warts, PIN grades 1/2/3, and AIN grades by 76%, 80%, 21%, and 77%, respectively. Males, regardless of HPV status, were found to have reduction of external genital lesions, genital warts, PIN grades 1/2/3, and AIN grades 1/2/3 by 67%, 68%, 0.3%, and 50%, respectively.

Bivalent HPV Vaccine

In 2009, 3 years after FDA approval of the quadrivalent HPV vaccine, the FDA licensed a second vaccine to prevent HPV-associated diseases due to HPV types 16 and 18. The bivalent vaccine is an HPV-16/18 VLP-based, AS04-adjuvanted vaccine given as a series of three 0.5-mL intramuscular injections given at 0, 1, and 6 months. The bivalent vaccine is FDA approved for use in girls and young women aged 9 through 25 years. The vaccine is prepared by combining adsorbed VLPs (L1 proteins) of HPV types 16 and 18 together with a novel AS04 adjuvant system (3-*O*-deacyl-4'-monophosphoryl lipid A [MPL] adsorbed onto aluminum) in sodium chloride, sodium dihydrogen phosphate dihydrate, and water to stimulate a humoral immune response (IgGs against HPV-L1 capsid proteins).⁶⁰

The vaccine is used for prevention of the following HPV-associated diseases *due to vaccine type* HPVs in females:

- Cervical cancer
- CIN grades 1/2/3 and AIS

Bivalent Vaccine Efficacy

The efficacy of the bivalent vaccine was assessed in two double-blinded, randomized controlled trials, together evaluating over 19,000 young women aged 15 to 25 years, most notably the PATRICIA (PApilloma TRIal against Cancer In young Adults) trial of vaccine efficacy for both according to protocol (ATP) and total vaccinated cohort (TVC) populations.^{154,194} Presence of CIN grades 1/2/3 or AIS served as efficacy endpoints to assess prevention of cervical cancer. Persistence of infection past 12 months served as the virologic endpoint.

Primary analysis included an ATP population, or HPV-naïve population, consisting of women ages 15 through 25 years who received all three vaccine doses, who were HPV naïve to HPV-16 and HPV-18 at baseline and at 6 months, and for whom all efficacy measures were available. Vaccine efficacy for the prevention of HPV type 16- or 18-related CIN grades 2/3 or AIS and CIN grades 1/2/3 or AIS was 93% and 92%, respectively. Also within the ATP cohort, the vaccine reduced persistence of infection at 12 months by 91%.^{154,194}

Further analysis included HPV-naïve and nonnaïve females (those with current infection and/or previous exposure) and the TVC, including females who received at least one vaccine dose, for whom all efficacy measures were available, regardless of HPV status. Females who were HPV naïve (negative for 14 oncogenic HPV types 6, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68) at day 1 were found to have vaccine efficacy for CIN grades 1/2/3 or AIS, CIN grades 2/3 or AIS, and CIN grade 3 or AIS of 97%, 98%, 100%, respectively. Females regardless of vaccine-type HPV status were found to have vaccine efficacy for CIN grades 1/2/3 or AIS, CIN grades 2/3 or AIS, and CIN grade 3 or AIS of 56%, 53% and 34%, respectively. Females regardless of all-type (vaccine + nonvaccine) HPV status were found to have vaccine efficacy for CIN grades 1/2/3 or AIS, CIN grades 2/3 or AIS, and CIN grade 3 or AIS of 22%, 30%, and 33%, respectively.^{154,194}

9-Valent Vaccine

To increase the scope of protection against the range of oncogenic mucosal HPV types, a 9-valent L1 vaccine has been produced by the manufacturer of the quadrivalent vaccine.^{242,277}

The 9-valent HPV vaccine contains the same L1 virus-like particles as the quadrivalent vaccine (based on HPV types 6, 11, 16, and 18) plus L1 virus-like particles based on HPVs types 31, 33, 45, 52, and 58. In clinical trials, the efficacy of the 9-valent HPV vaccine for prevention of the combined endpoint of HPV 31-, 33-, 45-, 52-, and 58-related CIN2/3, AIS, cervical cancer, VIN2/3, VaIN2/3, vulvar cancer and vaginal cancer was 96.7%.¹²⁷ In many regions, including North America and Europe, use of the 9-valent vaccine is now supplanting use of the bivalent and quadrivalent vaccines.

Two-Dose HPV Vaccination Regimens

While the initial licensure trials of the bivalent, quadrivalent, and 9-valent HPV vaccines all used 3-dose immunization regimens, immunogenicity studies of all 3 vaccines suggest that a 2-dose regimen, with the first and second dose administered 6 months apart, induces a noninferior antibody response to all vaccine antigens.^{93,192,335}

The possibility of an effective 2-dose HPV vaccination regimen improves the prospects for widespread HPV vaccine use in the low- and middle-income countries. It should be noted, however, that licensure of HPV vaccines has been based on proven efficacy for prevention of HPV-associated diseases. To date, the rationale for 2-dose vaccine regimens is based solely on immunogenicity noninferiority; vaccine efficacy data are not yet available. As such, widespread implementation of two-dose vaccine regimes warrants some degree of caution.⁹⁵

Population Effectiveness of HPV Vaccines

Data from several national vaccination programs suggest that widespread HPV immunization leads to substantial reductions in the prevalence of genital warts and in the prevalence of HPV infection. For examples, see Canvin et al.⁵² and Markowitz et al.²¹⁸

HPV vaccines also appear to induce substantial herd immunity, conferring protection to nonimmunized population members.⁹⁷

HPV Vaccine Safety

From the perspective of vaccine safety, HPV vaccines stand as some of the most widely studied vaccines in history. While there have been substantial concerns about HPV vaccine safety expressed on the Internet and in the lay press, large, well-designed postmarketing vaccine safety surveillance studies of HPV vaccine safety have confirmed findings of the vaccine licensure trials; most HPV vaccine-associated adverse events are at the immunization site and are predominantly pain, swelling, and erythema.^{127,60} Postlicensure studies have shown that syncope and possibly skin infections are associated with HPV vaccination. Surveillance for serious adverse events—such as adverse pregnancy outcomes, autoimmune diseases (including Guillain-Barré syndrome and multiple sclerosis), anaphylaxis, venous thromboembolism, and stroke—were extensively studied and have shown no increase in the incidence of these events compared with background rates.^{11,134,206,208,341,373}

HPV Vaccine Immunogenicity in Immunocompromised Patients

Studies of HPV vaccine immunogenicity in immunocompromised hosts have demonstrated a very slightly lower rate of seroconversion in comparison to immunocompetent patients. However, antibody response in immunocompromised patients is still robust. A number of studies have been published in the HIV-positive population. In children 7 to 12 years of age, 97% to 100% seroconversion was observed in children vaccinated with the quadrivalent vaccine.¹⁹⁶ However, a decrease in titers 72 weeks following administration of the last vaccine (>76% antibody seropositivity persisted) was noted in another study, raising the question that perhaps booster doses may be beneficial in this population.³⁸² In HIV-positive men, greater than 95% seroconversion of all 4 vaccine types occurred with administration of the quadrivalent vaccine (this study population had a median CD4 count of 517; 97% had a viral load less than 10,000 copies per mL).³⁸⁶ Recently, Faust¹⁰⁶ demonstrated a 100% seroconversion in HIV-positive subjects following administration of a bivalent HPV vaccine. In comparison, vaccination with a quadrivalent vaccine led to 95% to 100% seroconversion of types 6, 11, and 16 and 73% seroconversion of type 18.¹⁰⁶ Studies in other immunocompromised populations are scant. Results show a lesser response to vaccine; nonetheless, seroconversion was demonstrated. In patients with systemic lupus erythematosus, vaccination with quadrivalent HPV vaccine showed a 76% seroconversion rate.²²⁸ In adult solid-organ transplant patients, 52.6% to 68.4% seroconversion was noted depending on HPV type (only 47% had evidence of seroconversion to all 4 types).¹⁸⁶ Most studies noted lower antibody titers in immunocompromised subjects than in immunocompetent hosts, though it remains unclear if antibody concentration is clinically significant. More studies of HPV vaccine immunogenicity and effectiveness in immunocompromised patients are needed.

Vaccine Limitations

With widespread use, HPV vaccines offer the exciting prospects of substantial reductions in HPV-associated morbidity and mortality. However, as with other vaccines, quadrivalent and bivalent HPV vaccines have specific limitations. It is important to consider the following limitations when giving these vaccines:

- HPV pseudovirion-based vaccines do not eliminate the need for continued routine cervical and anal cancer screening.
- HPV vaccines do not provide protection against or change the natural history of established infections due to vaccine and nonvaccine HPV types. Although, interestingly, while virus-like, particle-based HPV vaccines are considered preventive (as opposed to therapeutic), previous quadrivalent HPV vaccination of women who had surgical treatment for HPV-related disease significantly reduced the incidence of subsequent HPV-related disease, including high-grade disease.¹⁷³
- The vaccines are not intended to treat active external genital lesions; any intraepithelial lesion type; or cervical, vulvar, vaginal, and anal cancers.

Although most HPV-associated head and neck malignancies are attributable to HPV type 16 and 18 infections, there are currently no data demonstrating that HPV immunization impacts the incidence or course of HPV-associated head and neck malignancies. Similarly, although it is anticipated that HPV immunization with the quadrivalent vaccine will reduce the incidence of HPV type 6- and HPV type 11-associated laryngeal papillomatosis, there are no data indicating that the quadrivalent vaccine will prevent or alter the clinical course of laryngeal papillomatosis at this time.

The overall personal and public health and economic benefits of vaccination have been well demonstrated in both males and females.^{65,102,181} The importance of both male and female prevention efforts resides in the fact that not only is there disease burden in women and men alone but there is also significant opportunity for transmission and infection of the other, potentially leading to significant morbidity and mortality (e.g., as evidenced by the increased frequency of CIN in females with partners with penile lesions).^{77,140,149,163,175,334,365}

Vaccine benefits vary according to the population immunized. In populations that are provided regular cervical cytology screening, HPV

immunization serves largely to prevent high-grade dysplasia and to reduce the economic and emotional costs associated with treatment of premalignant disease. In resource-poor populations that are unscreened, HPV vaccines benefit by preventing cervical cancer and its associated economic and emotional expenses.^{77,83}

Based on trends in sexual behaviors, age of sexual debut, knowledge that acquisition of HPV infection occurs within first few years of sexual debut, and the fact that vaccination is most efficacious in HPV-naïve individuals, initiating vaccination prior to any sexual contact (vaginal, anal, oral, digital) will prevent the most infections and their sequelae.²⁷ It becomes the responsibility of any primary care provider of children, adolescents, and young adults to discuss HPV infection with both patients and their caregivers and to offer vaccination to patients as early as possible to prevent as much disease as possible.⁸¹

SUBSECTION III DNA—*Adenoviridae*

156

Adenoviruses

Tempe K. Chen • James D. Cherry

Adenoviruses, which are responsible for a varied array of illnesses in children,^{*} are associated most commonly with respiratory illness and gastroenteritis, but cardiac, neurologic, cutaneous, urinary, and lymphatic manifestations also occur frequently. Although many of the clinical manifestations of adenoviral infections are distinctive, the specific viral etiologic agent rarely is recognized by physicians.

Adenoviruses were noted first in explant cultures of human adenoid tissue; this finding, plus the observation of their apparent general affinity for lymphatic tissue, led to the designation of their name.^{178,186,214,585}

^{*}References 2, 3, 70, 72, 107, 176, 214, 308, 315, 392, 574, 589, 621, 673.

HISTORY

The first adenoviral strains were not isolated until 1953, when tissue culture techniques became available, although epidemic disease caused by adenoviruses had been observed throughout the first half of the 20th century. Epidemic keratoconjunctivitis first was noted and reported in Austria by several physicians in 1889.^{4,220,563,599,632} Major outbreaks of epidemic keratoconjunctivitis were reported in Bombay in 1901, in Madras in 1920 and 1928, in Hawaii in 1941, and on the West Coast of the United States in 1942.^{290,311,312,378,727}

Epidemics of illness such as pharyngoconjunctival fever were observed throughout the 20th century. Béal³⁷ in 1907 was the first to report the

swimming pools

syndrome; in the 1920s, epidemics associated with swimming in public pools and in lakes were noted in Germany and the United States.^{30,523} Initial studies by Rowe and colleagues⁵⁸⁵ revealed cytopathic changes in explant tissue cultures of human adenoids that had been removed surgically. Fluid from these cultures caused distinctive cytopathologic changes in other tissue cultures, and antiserum prepared in hyperimmunized rabbits neutralized the effect. In 1954, Hilleman and Werner³⁰⁵ isolated similar cytopathic agents from the throat washings of military recruits with febrile acute respiratory disease. Shortly thereafter, epidemic keratoconjunctivitis and pharyngoconjunctival fever were seen to be illnesses of adenoviral etiology.^{139,142–144,335}

Initially, adenoviruses were known by the following names: adenoid degeneration (AD) agent because of its recovery in human adenoid tissue explants⁵⁸⁵; respiratory illness patient number 67 (RI-67) agent, which was recovered from a military recruit with primary atypical pneumonia during an epidemic of acute respiratory disease^{304,305}; adenoidal-pharyngeal-conjunctival (APC) agent³²¹; and acute respiratory disease (ARD) agent.¹²² In 1956, investigators in the field selected the term *adenovirus* for the new group of viruses. The name suggested the characteristic involvement of lymphadenoid tissue, as well as the tissue from which the organism was first isolated.¹⁷⁸

Because of considerable morbidity and major economic considerations related to adenoviral epidemic respiratory disease in military recruits, the development of vaccines received early attention. Initially, inactivated vaccines were produced, and they achieved some degree of success.^{266,303,406} Later, live viral preparations grown in diploid human fibroblast tissue culture became available and proved quite successful in controlling specific adenoviral infections in the military services.*

In 1975, enteric adenoviruses (adenovirus types 40 and 41) first were reported.^{182,601,713} They were demonstrated by electron microscopy and subsequently were shown to be a significant cause of diarrhea in children.^{70,116,391,472,524,655,669,673} Particularly important today are adenoviral infections in immunocompromised hosts, particularly transplant recipients.³⁸³

PROPERTIES OF THE VIRUS

Classification

Adenoviruses that infect humans are placed in the family *Adenoviridae* and the genus *Mastadenovirus*.^{197,313,463,604} At present, more than 70^{271,421,435} immunologically distinct adenoviral types have been recovered from humans.[†] Additional adenoviral types have been isolated from monkeys, cattle, dogs, mice, and chickens.^{293,295–297} Mammalian adenoviruses have a common generic antigen that can be identified by complement fixation and enzyme-linked immunosorbent assay (ELISA).^{342,539,576,715} Individual serotypes are identified by neutralization.^{274,279,375} Adenovirus type 52, the first human adenovirus identified based on genetic analysis, was also classified as a novel species human adenovirus G. Subsequent types have been identified by bioinformatic analysis of genomic sequences.⁴²¹

Adenoviruses originally were subclassified on the basis of four hemagglutination patterns with rat and rhesus monkey red blood cells.⁵⁸¹ This subclassification is updated in Table 156.1. In 1962, researchers found that adenovirus type 12 could cause tumors in hamsters, and soon thereafter, investigators realized that adenoviruses also could be classified by their oncogenic potential in rodents.^{319,662} Grouping by oncogenic potential was similar, with few exceptions, to grouping by hemagglutination properties: organisms in hemagglutination group I had moderate oncogenic potential, group II and group III organisms had low or no potential, and group IV organisms had high oncogenic potential.^{245,314,327}

Adenoviruses also have been subclassified (A to G) on the basis of the percentage of guanine plus cytosine in their DNA and other biochemical and biophysical criteria^{299,373,546,600,696–698} (Table 156.2). In general, subgroup A organisms are the same as hemagglutination group IV; subgroup B, the same as hemagglutination group I; subgroups C, E, and F, the same as hemagglutination group III; and subgroup D, the

TABLE 156.1 Separation of Human Adenoviruses Into Subgroups by Ability to Agglutinate Rhesus Monkey and Rat Erythrocytes

Subgroup	Characteristic	Type
I	Complete agglutination of monkey erythrocytes	3, 7, 11, 14, 16, 21, 34, 35, 50
II	Complete agglutination of rat erythrocytes	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51
III	Partial agglutination of rat erythrocytes	1, 2, 4–6, 40, 41
IV	No or little agglutination of monkey or rat erythrocytes	12, 18, 31

Data from references 147, 293, 299, 307, 310, 358, 373, 406, 508, 509, 600, 716.

TABLE 156.2 Human Adenoviral Serotypes Based on Biochemical and Biophysical Criteria

Subgroup	Adenovirus Type(s)	Location and Manifestations of Infection
A	12, 18, 31, 61	Gastrointestinal; may cause disease in children
B:1	3, 7, 16, 21, 50, 55, 66	Respiratory, eye, and gastrointestinal symptomatic infections
B:2	11, 14, 34, 35	Urinary and respiratory; symptomatic urinary tract infections (particularly in immunosuppressed patients) and symptomatic respiratory infections
C	1, 2, 5, 6, 57	Respiratory and gastrointestinal; symptomatic respiratory infections and hepatitis in immunosuppressed patients
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51, 53, 54, 56, 58–60, 63–67	Eye and gastrointestinal; symptomatic eye infections, gastrointestinal infections in HIV-infected patients
E	4	Symptomatic eye and respiratory infections
F	40, 41	Symptomatic gastrointestinal infections
G	52	Symptomatic gastrointestinal infections

Data from references 147, 299, 314, 373, 406, 421, 425, 546, 571, 573, 600, 697, 704.

same as hemagglutination group II. Restriction enzyme analysis has resulted in genomic typing of specific adenoviral serologic types.⁴¹⁶ In particular, numerous genotypes of adenovirus type 7 have been identified, and the severity of disease may relate to the genotype.

Physical Properties

Adenoviruses are nonenveloped DNA viruses 65 to 80 nm in diameter.^{197,245,313,314,327,382,463} The virion consists of a protein capsid composed of 252 capsomeres and a nucleoprotein core that contains the DNA viral genome and two to four internal proteins.⁵⁵⁴ The virion is roughly spherical in the form of an icosahedron; each of the 20 sides is an equilateral triangle, with the vertices of each converging in groups of five and resulting in 12 pentagonal vertices.^{70,214,313} Each vertex capsomere contacts five other capsomeres and is designated a penton. Each penton contains a base plate and a rodlike projection, the fiber. The virion has 240 nonvertex capsomeres that occur in groups of six and are known as hexons.^{382,509,672} Hexons contain the generic complement-fixing antigen.²¹⁴ Each capsomere has a diameter of 8 nm and a central hole that is 2 to 3 nm in diameter.⁷²¹ The capsomeres constitute 87% of the dry weight of the virion.

*References 166, 168, 255, 271, 351, 407, 421, 434, 451, 572, 573, 580, 620, 656, 659.

†References 107, 130, 141, 168, 207, 208, 210, 212, 213, 228, 263, 425, 494, 495, 506.

The central core of the virion, which accounts for 12% to 14% of its dry weight, is composed of linear double-stranded DNA (molecular mass, 23.85×10^6 Da for adenovirus type 2) and two to four basic proteins.^{222,314,721}

Adenoviruses are highly stable in general.^{151,214,243,327,409} They are resistant to lipid solvents and retain activity at pH values ranging from 2 to 10. They can be inactivated upon exposure to sodium hypochlorite for 10 minutes or to 85% ethanol for at least 2 minutes.⁴⁵²

At 24°C, maximal infectivity is maintained between pH 6 and 9.5. Adenoviruses are stable at room temperature for 2 weeks, at 36°C for 7 days, and at 4°C for at least 70 days. Infectivity is destroyed by heating to 56°C for 30 minutes. Sodium dodecyl sulfate (0.25%) inactivates virus by disruption of the capsid.³⁸² Hydrogen peroxide vapor has been shown to inactivate adenoviruses⁵¹ and free chlorine is effective in controlling adenoviruses in drinking water.⁵²⁵ Adenovirus serotypes 2, 10, 40, and 41 are highly resistant to ultraviolet radiation, and, therefore, they can be used as markers of the quality of water treatment practices.³⁰²

Antigenic Composition

The antigenic determinants of adenoviruses are contained on the protein structural subunits (hexons, pentons, and fibers).⁶⁷² The hexon antigen (alpha component) carries the generic antigenic component that is common to all mammalian adenoviruses and is measured by complement fixation or ELISA. Another hexon antigen (epsilon component) reacts with neutralizing antibodies lacking hemagglutination-inhibiting activity. The antigen related to viral fiber also induces the production of type-specific neutralizing antibody for some adenoviral types. Minor antigens are related to the pentons. One of them (the cell-detaching factor) causes rounding and clumping of tissue culture cells.

Gerna and associates,²⁴¹ using the immunoperoxidase antibody technique, found that the early antigens of all serotypes belonging to one group (see Table 156.1) react strongly with all type-specific immune sera of the same group.

Tissue Culture Growth

Although adenoviruses can be grown in a wide variety of cells of human epithelial origin, primary or diploid cultures of human embryonic kidney are preferable for recovery of agents from clinical specimens.⁴⁰⁹ Continuous cell lines such as HeLa and HEP-2 also are quite sensitive.^{288,327,570,586} Adenoviruses will grow in monkey kidney tissue culture, but evolution of the cytopathic effect is considerably slower than that occurring in cells of human origin. In addition, the cytopathic effect is more variable in monkey kidney tissue culture, and many isolates will be missed.

Enteric adenoviruses have been detected in human feces by electron microscopy.* These enteric adenoviruses, identified as types 40 and 41, usually do not grow in standard tissue culture systems. Both viral types will grow in Graham 293 cells (a human embryonic kidney cell line transformed by adenovirus type 5); type 40 also will grow in tertiary monkey kidney cells, and some strains of type 41 will grow in HEP-2, Chang conjunctiva cells, and tertiary cynomolgus cells.^{546,699} Grabow and associates²⁵⁸ noted that the PLC/PRG/5 cell line was 100 times more sensitive to a laboratory strain of adenovirus type 41 and 10 times more sensitive to a laboratory strain of adenovirus type 40 than were Graham 293 cells.

Specimens for viral culture may be obtained from the eye, pharynx, blood, lungs, pleural and pericardial fluid, liver, stool, intestinal epithelium, lymph nodes, cerebrospinal fluid (CSF), brain, urine, and renal tissue. For best isolation rates, clinical specimens should be inoculated in cell culture within 6 hours of being collected. Tissue culture tubes are incubated best at 37°C, and rolling offers no advantage over stationary incubation.⁴⁰⁹ Although the cytopathic effect has considerable variability, the most consistent finding is marked rounding and clumping of cells, often in grapelike clusters.^{554,558} A cytopathic effect may be noted as early as 1 to 2 days after inoculation, but it may be delayed as long as 4 weeks. Use of the shell viral technique, in which infected cells in a specimen are centrifuged onto HEP-2 tissue culture cells, yields positive cultures in 1 to 2 days.¹⁸³ The cytopathic effect characteristically is

followed by detachment of the entire cell sheet from the glass of the tissue culture tube within 2 to 4 days.^{263,290,540,583,586}

Virus Multiplication

Initial attachment of adenoviruses to cells is relatively slow, with up to 6 hours being required.^{140,244,327} The fiber protein of the virus mediates attachment to the cellular receptor.⁶⁰⁶ An important adenovirus receptor is the coxsackievirus and adenovirus receptor (CAR) protein. It is a high-affinity receptor for all adenoviral subgroups except subgroup B. Penetration into the host cell occurs rapidly, either by phagocytosis or by direct entry through the plasma membrane.^{327,430} The eclipse period with adenoviruses varies from 11 to 21 hours, depending on the serotype.^{244,327} During eclipse, viral DNA uncoating requires approximately 2 hours when determined biochemically.³²⁷ After uncoating, the viral DNA rapidly enters the nucleus of the cell and disassociates from its internal protein.^{140,245,430} After the eclipse period, viral DNA accumulates, often doubling the content of the infected cell and becoming part of the typical inclusion bodies of the infected cells.²⁴⁵

Characteristic cytopathic changes in tissue culture, as demonstrated by light microscopy of hematoxylin and eosin-stained material or by electron microscopy, appear as early as 8 to 24 hours after infection occurs.^{66,68,274} Two types of intranuclear alterations may be seen. In the first type, early, small, discrete eosinophilic inclusions are observed. They gradually enlarge, become more prominent, and then form a large crystalline central mass surrounded by a clear zone or halo.^{66,252} This type of early cytopathic effect appears to take place in cells that contain only small amounts of infectious virus.⁶⁷ The second type of intranuclear alteration, which generally occurs later, consists of large basophilic intranuclear inclusions.⁶⁶ Occasionally, giant forms measuring greater than 14 mm across are noted.⁶⁶ These mature inclusions may expand the nucleus of the cell so greatly that the cell's DNA content is 10 times larger than that of an uninfected cell. They contain a large amount of viral antigen and infective virus. Cytopathic changes vary considerably with the different adenoviral serotypes.^{68,382}

In general, virus remains within the nucleus of intact, infected cells, with less than 1% of the total viral content of a culture being free within the extracellular fluid at any one time.³⁸²

Animal Susceptibility

Human adenoviruses usually do not produce clinical illness in laboratory animals, although infections with several different serotypes have occurred in selected animals.³²⁷ When adenoviral strains were administered intranasally to young, "pathogen-free," colostrum-deprived pigs or 1-month-old cotton rats, pneumonia developed in the animals, and intranuclear inclusions were observed microscopically in their lungs.^{327,522} An adenovirus type 5 strain was injected intravenously into a rabbit, and the virus was recovered from the animal's spleen when removed 2 months later. Many adenoviral strains will propagate in a variety of different animal tissue cultures. In addition, in some cultures, marked cytopathic effects are observed, but little infectious virus is produced.

Adeno-Associated Viruses

Adeno-associated viruses are a group of small, replication-defective, single-stranded, nonenveloped DNA-containing, nonpathogenic virus-like particles of the *Parvoviridae* family that replicate in tissue culture only in the presence of adenoviruses.^{60,105,140,214,327,368,596,621} Twelve natural serologic types have been identified; however, only types 2, 3, 5, 6, and 9 have been recovered from humans.^{214,382,596} These agents have been isolated from throat and anal swab specimens of children from whom adenoviral strains also were isolated.⁶⁰ Approximately 30% of children have complement-fixing antibody to adeno-associated virus types 2 and 3; most of these children have had evidence of adenoviral infection as well.⁶¹ Neutralizing antibody to adeno-associated virus types 2 and 3 is noted in the sera of 60% to 80% of children 8 to 14 years of age.⁵³² The specific relevance of adeno-associated viruses is unknown. Adeno-associated viruses reliably insert genetic material at a specific site on chromosome 19. Research on their potential as viral vectors in recombinant gene therapy for disorders such as lysosomal storage diseases, spinal muscular atrophy, glycogen storage diseases, leukodystrophies, Parkinson disease, Alzheimer disease, and age-related macular

*References 70, 132, 148, 342, 373, 562, 575, 669, 697, 715.

degeneration is ongoing.^{596,617} To date, adeno-associated viral vectors have been successfully used as gene therapy in the treatment of hemophilia B, inherited night blindness, and lipoprotein lipase deficiency.³⁵⁷ A replication-competent, genetically engineered oncolytic adenovirus VCN-01 has demonstrated a potent antisarcoma effect with possible therapeutic application in combination with chemotherapy for treatment of osteosarcoma.⁴⁴⁶

EPIDEMIOLOGY

General Prevalence

Adenoviral infections account for 2% to 10% of all respiratory illnesses.* In children, adenoviruses are estimated to be responsible for 2% to 35% of respiratory viral illnesses,[†] and they are implicated in 5% to 17% of upper respiratory tract infections, 4% to 10% of cases of pharyngitis, 3% to 9% of cases of croup, 5% to 11% of cases of bronchitis, 2% to 16% of cases of bronchiolitis, and 4% to 11% of cases of pneumonia.^{69,87,98–100,216,233,330,486,534} Enteric adenoviral infections are the cause of 2% to 15% of acute diarrheal illnesses in children.[‡] Specific categories of illness caused by adenoviruses vary with respect to viral serotype, patient age, socioeconomic status, and environmental conditions.^{95,126,270,289,343,741} Adenoviruses have a predilection for infants and children younger than 5 years who spend portions of their days in closed environments, such as daycare centers, orphanages, and other institutions.^{44,47,95,280,429,694} Epidemics of disease caused by adenoviral infection have been associated with swimming pools, daycare centers, resident schools, certain industries, hospitals, physicians' offices, and early basic military training centers in young recruits.[§] Adenoviruses are recovered commonly from children in tropical countries and in situations characterized by crowding, such as lower socioeconomic settings.^{95,100,119,343,741}

Age, Incidence, and Prevalence

Although adenoviral infections occur in all age groups, the incidence of infection generally is related inversely to age.^{126,382} More than 90% of newborn infants have transplacentally acquired complement-fixing adenoviral serum antibody.^{499,633} Most infants have neutralizing antibody to one or more of the common adenoviral types, which appears to be protective during the first 6 months of life. When adenoviral infection does occur in a neonate, it often is severe and occasionally fatal.^{18,190,749} By the sixth month of life, only 14% of infants have demonstrable adenoviral complement-fixing antibody. By the time children reach 1 year of age, complement-fixing adenoviral antibody is observed in 44% to 50% of sera tested.^{321,504}

The incidence of adenoviral infection peaks in infants and children between 6 months and 5 years of age.^{114,470,541} By the time that they are 5 years of age, 70% to 80% of children have neutralizing antibody to adenovirus types 1 and 2, and 50% have antibody to adenovirus type 5.^{150,212,321,332,533,541,676}

Adenoviral infections also occur commonly in grade school- and junior high school-aged children, but the incidence diminishes in high school-aged adolescents. Adenoviral infections occur in only 1% to 2% of college students, and they are noted infrequently in civilian adults.^{184,185,187,262,636} Approximately 1% of adults with a respiratory infectious illness will have adenoviral infection; in hospitalized adults, the incidence is approximately 4%.²⁶² The most common adenoviral respiratory infections in children are caused by types 1, 2, 3, and 5.^{1,13,44,405,676,688,694} Types 6 and 7 are the next most frequent isolates associated with childhood respiratory infection. Adenovirus types 40 and 41 are the most common causes of diarrhea.^{116,389,413}

Military Recruits

Epidemic adenoviral disease occurs commonly in military recruits, with virtually all illness developing during the first 8 weeks of basic

training.^{211,384,439,461,588,590,678,679} The attack rate has varied between 40% and 90%.^{211,263,439,677} Adenoviruses account for 30% to 70% of acute respiratory disease, 67% of common cold-like illnesses, 62% to 77% of cases of acute febrile pharyngitis and tonsillitis, 67% of cases of bronchitis, and 24% of cases of pneumonia.^{50,210} Some adenoviral infections are associated with minimal or no symptoms.^{210,263}

A vaccine against adenovirus serotypes 4 and 7 was developed for use in military basic training centers and effectively prevented outbreaks of adenovirus. Routine vaccination began in 1971, but the sole manufacturer of the vaccine ceased its production in 1995. The first large post-vaccine era outbreak of adenovirus serotypes 3 and 7 occurred in naval recruits in Great Lakes, Illinois, in 1997.⁵⁹⁰ Subsequent adenoviral epidemics occurred in military recruits in Fort Jackson, South Carolina, in 1998 with type 4, and in Lackland Air Force Base in San Antonio Texas, in 2007 with serotype 14.^{75,650,693}

The last remaining stocks of vaccine were depleted or expired by 1999. Because of continued outbreaks, vaccine development was reinitiated, leading to the development of a live oral vaccine against adenovirus 4 and 7. The vaccine was licensed for military personnel ages 17 to 50 years in March 2011. It is currently manufactured by Barr Labs and distributed via Teva Pharmaceuticals.⁶⁶⁷ A full review of eight deaths caused by adenovirus infection in military recruits from 1999 to 2010 was published by Potter and colleagues. All eight deaths occurred after the cessation of the immunization program in 1999. In contrast, there were no deaths due to adenovirus in US military members from 1975 to 1998 while this program was in place.⁵⁵³ Koren and colleagues³⁸⁷ conducted an observational, longitudinal study of 1536 children and adults under 65 years of age at five US-based military medical centers from September 2009 through May 2014. They found that adenovirus accounted for 2.8% of cases of influenza-like illness that was described as relatively mild (e.g., no hospitalizations or deaths reported). Coinfection was identified in 51.1% of cases, with 27.3% of coinfections identified in adults. Kajon and coworkers³⁵⁰ sought to describe the molecular epidemiology of adenovirus type 21 causing febrile respiratory illness among US military recruits from 1997 to 2011. Adenovirus type 21 is the predominant source of adenoviral illness when circulation of adenovirus types 4 and 7 is well controlled by vaccination. As such, it is possible that it may become an active pathogen again following re-introduction of the vaccine.

Geographic Distribution

Adenoviral infections have been noted throughout the world.* Epidemic, endemic, and sporadic infections all occur.

Seasonal Patterns

Sporadic infections with adenoviruses occur throughout the year.^{212,217,251,307,320,428,440,476,486} Epidemic adenoviral respiratory disease usually occurs in the winter, spring, and early summer.[†] Seasonal patterns depend on serotypes, population groups, and exposure. Epidemics of disease in military recruits commonly associated with adenovirus types 4 and 7 occur most frequently in the winter and spring.^{62,211,210,303} Epidemics of pharyngoconjunctival fever have been noted most commonly in the summer months in school-aged children in association with summer camps or swimming pools.^{447,680,721} No seasonal pattern has been identified for adenoviral gastroenteritis.^{132,372,575,669}

Host and Social Factors

The overall incidence of adenoviral illnesses is higher in males.^{126,290} In a study involving 3313 adenovirus isolates, the male-to-female ratio was 1.3:1.¹²⁶

Susceptibility to adenoviral infection apparently does not vary by race. More severe disease has been noted in infants of native and Indian populations in New Zealand and Canada.^{9,40,253} However, the relationship of these findings to socioeconomic conditions was not identified initially.

The incidence of adenoviral infection is greatest in lower socioeconomic population groups.³⁴³ Spread of infection has been observed in daycare centers, schools, children's homes, hospitals, clinics, physicians' offices, and certain industrial settings.* Acute overwhelming illness, including bronchiolitis and pneumonia with severe pulmonary residua, has been reported in neonates, small infants, and occasionally, adults.^{18,289,412} Adenoviral infections are a significant problem in immunocompromised hosts; when they occur, they frequently are severe and occasionally are fatal.[†]

Spread of Infection

Adenoviruses frequently are isolated from the conjunctiva, throat, and stool. Despite the ease of isolating the virus, the effectiveness of spread of infection in the general population varies considerably.¹⁰⁰ Adenovirus types 1, 2, 3, 5, and 7 are effective spreaders; however, they are not as highly contagious as varicella, measles, and influenza viruses.^{99,100} Close contact appears to be necessary for infection to spread from one person to another.⁶³³ Illness does not spread rapidly in the usual school setting but does spread dramatically in closed environments.^{47,99,280,320} Although adenovirus type 4 spreads less effectively in the general population, spread is rapid in nonimmune military recruits who live in close contact with each other.¹¹² In an outbreak of adenovirus type 7 in a children's home, 84% of the residents were shown to be infected.

Transmission of virus occurs by droplets reaching the conjunctiva, nose, or throat or, alternatively, by the fecal-oral route. In volunteer studies, adenoviruses have been shown to spread by small-droplet aerosols and, to a lesser degree, by large droplets.^{21,127,128} Adenovirus type 4 has been recovered from room air and cough samples of patients with the virus in their throats.²² A study by Russell and colleagues⁵⁸⁷ of 341 military recruits and support personnel at the Marine Corps training center in San Diego, California, demonstrated that more than 79% of incoming recruits were susceptible to adenoviral infection in the postvaccine era. They identified incoming recruits with prolonged asymptomatic shedding of adenovirus and the presence of adenoviruses on multiple living quarter surfaces as potential sources of transmission. They also found evidence of extended pharyngeal shedding of adenovirus over the course of several days among recruits who had febrile respiratory illnesses.

In epidemics of pharyngoconjunctival fever, the virus appears to spread from contaminated swimming pool water to the eyes of recipients. In non-swimming-associated outbreaks of adenoviral respiratory illness with appropriate serotypes, conjunctivitis occurs only rarely.^{31,47,208,280,345,379} This fact, in conjunction with the finding that pharyngoconjunctival fever occurred after conjunctival administration of virus, but not after nasopharyngeal application in volunteers,^{43,621,708} suggests that the conjunctiva must be inoculated directly for the syndrome to occur. Epidemics of keratoconjunctivitis have occurred as a result of contact with contaminated ophthalmic instruments and fingers.^{33,142,304,335,337,360,381,476,626} In daycare centers, orphanages, and the military, transmission probably occurs most commonly through small-droplet aerosols in crowded quarters.⁵⁴⁸ An alternative in children is the fecal-oral route. Enteric adenoviruses have been identified in fecal specimens for approximately 8 days after the onset of gastroenteritis.³⁷²

Family members may excrete adenoviruses in their feces intermittently for prolonged periods after initial infection.^{72,212} In one study, 20% of persons excreted adenoviruses in stool for longer than 3 months. Intrahousehold spread appears to continue as long as susceptible family members are present.²¹² Infants born into households in which members are adenoviral fecal excretors often become infected, presumably through the fecal-oral route. In general, 50% of susceptible household members will experience infection, although the rate varies inversely with age and also depends on the serotype of adenovirus. Reinfection with specific adenoviral serotypes occurs, but most are asymptomatic or associated with only minimal illness.

Nosocomial spread of both respiratory and enteric adenoviruses is a common occurrence and has been the cause of fatal illnesses in infants and immunocompromised patients.^{5,153,203,386,618,749} DNA viruses are known

to be more stable than RNA viruses and have been considered a good indicator of viral contamination when assessing the quality of cleaning of environmental surfaces in the hospital environment, even in a nonoutbreak setting.⁵²⁶ Ganime and colleagues^{230,231} analyzed 480 fomite samples collected over a 1-year period from the neonatal intensive care unit and general pediatric ward for both adenoviruses and rotavirus species A. They found that adenovirus was detected more frequently in the pediatric ward (38% in pediatric ward vs. 3.2% in neonatal intensive care unit). They attributed this difference to the fact that adenoviruses are more stable in the environment and can remain viable for 7 to 90 days, thereby highlighting a possible role for fomite transmission in the healthcare setting. They emphasized the importance of assessment of hand hygiene adherence, as well as regular assessment of the efficacy of disinfectant solutions and cleaning practices in the healthcare setting.

PATHOGENESIS AND PATHOLOGY

Adenoviral infections usually are acute and self-limited, and, therefore, opportunities to study the pathogenesis and pathologic process have been infrequent. Study of the pathologic mechanisms has been performed in human volunteers, tissue and organ culture systems, and recent murine model systems and by examination of specimens from persons dying of adenoviral disease.

Viral Infection

In general, the characteristics of adenoviral infection depend on the host and the serotype of the agent.* The route of infection with adenoviruses that are capable of causing pharyngoconjunctival fever determines the pathologic manifestations. In most respiratory illnesses, initial viral infection occurs in the respiratory tract and involves the mucous membranes of the nose, oropharynx, and conjunctiva. Adenoviral agents have been isolated from sputum and oral secretions from 2 days before the onset of clinical illness to up to 8 days after the onset of symptoms. Deeper respiratory involvement of the trachea, pleurae, and lungs may result from initial small-particle aerosol, from progression of local infection, or perhaps as a result of viremia. Gastrointestinal infection in conjunction with respiratory infection also occurs early and probably is the result of swallowed virus. Stool isolates of respiratory viral types frequently are noted concomitantly with respiratory tract infection. However, in contrast to the upper respiratory infection, the virus may persist for a long time in the lower gastrointestinal tract. Infection with enteric adenoviral types is presumed to involve intestinal epithelial cells. In one fatal infection, adenoviral antigen was demonstrated in jejunal cells.^{562,714}

In experimental studies with aerosolized adenovirus type 4, recovery of virus from throat specimens occurred on day 5 or 6, progressed to a maximum concentration on day 11 or 12, and was seen uncommonly after day 20. Maximal recovery of adenovirus type 4 from anal specimens occurred on day 13, and shedding continued for longer than 3 weeks. Adenovirus types 26 and 27 inoculated into the conjunctiva resulted in short-term isolation of virus from the eyes on days 3 to 7 and, less frequently, from the throat on day 4.³⁵⁹ Isolation of virus from the rectum was common beginning at the end of the first week. Maximal fecal shedding occurred during the second and third weeks.

Like other DNA viruses, adenoviruses can establish latent infection in lymphoid tissues, particularly in T lymphocytes.²³⁶ Garnett and colleagues²³⁷ studied adenoidal and tonsillar tissue from children 1 to 19 years of age undergoing elective tonsillectomies for tonsillar hypertrophy, recurrent bacterial infections, or recurrent otitis media. Among 243 samples from 203 patients, they detected species C adenovirus DNA in 78% of samples, with peak detection at age 4 years, followed by decreasing frequency with increasing donor age. Interestingly, although adenoviral DNA was detected, infectious virus was isolated from culture in only 12.2% of samples. Not surprisingly, adenoviruses were more commonly found in adenoidal tissue when compared to tonsillar tissue. Faden and colleagues¹⁸⁹ subsequently conducted a prospective study of 59 children undergoing elective tonsillectomy and adenoidectomy. They also noted

*References 44, 47, 50, 97, 110, 190, 270, 274, 337, 521, 524, 535, 618, 673, 744.

†References 88, 91, 136, 141, 204, 264, 383, 431, 468, 513, 625, 749.

*References 49, 72, 77, 121, 247–249, 499, 549, 629, 713, 726.

a very high rate of asymptomatic infection in the adenoids and tonsils of such children. Viruses were detected in 70.9% of tonsils and 94.7% of adenoids, with adenovirus being the most common virus detected overall and the most commonly detected virus in adenoids (71.4%). The authors theorized that chronic stimulation of both tonsillar and adenoidal tissue is associated with obstructive airway disease. Alkhalaf and colleagues¹⁴ conducted a similar study and proposed that DNA methylation of adenoviral DNA might contribute to establishment of latency, which ultimately was not confirmed. Yeshuroon-Koffler and coworkers⁷³⁷ compared adenotonsillar tissue of 56 patients who underwent tonsillectomy and adenoidectomy for obstructive sleep apnea or recurrent throat infections. Viral DNA was detected in 50% of samples removed from patients with obstructive sleep apnea, but none in the recurrent infection group, thereby highlighting a possible role for adenoviral infection in the pathogenesis of obstructive sleep apnea.

Viremia is a common finding in uncomplicated adenoviral respiratory infections in children. In a study involving 68 children, adenoviral DNA was noted in acute-phase serum samples from 28 (41%) of these children.² In the children with primary infection, 72% (21 of 29) had adenoviral DNA in their acute-phase serum samples. Other evidence of the presence of adenoviruses in the bloodstream early in disease is the occurrence of maculopapular, morbilliform, or petechial exanthems (or any combination of such rashes), as well as recovery of virus from multiple organs such as the brain, kidney, urinary bladder, lymphoid tissue, and liver and at postmortem examination.⁴ The virus has been cultured from the mononuclear cells of heparinized blood.¹⁷

Coinfections

With the expanded use of direct fluorescent assays and PCR, investigators are discovering a common prevalence of coinfections of adenoviruses with multiple serotypes,³⁶ with other viruses,^{152,160,301,402,705} and with bacteria.⁵⁷ As technology is improving and made more available, the epidemiology of coinfection, as well as its impact on disease, is becoming clearer. Calvo and colleagues⁸⁷ conducted a prospective study of children admitted to the hospital with acute respiratory infections. Adenovirus was detected in 403 out of 2371 confirmed viral infections with a 62% rate of coinfection. Approximately 49% experienced coinfection with RSV and 24% experienced coinfection with enterovirus and rhinovirus. A large international cohort study of 3717 influenza-like illness episodes in 2421 pediatric patients ages 6 months to 10 years in 17 sites in eight countries found adenovirus coinfection with bocavirus to be most frequent.⁶⁵² Studies by Song and colleagues have demonstrated that 55% to 63% of pediatric patients have respiratory adenovirus coinfection.^{623,624}

Pathology

Early pathologic changes are observed in the epithelium of the respiratory tract. The severity of adenoviral involvement varies with the different serotypes. In tracheal organ cultures, growth of adenovirus type 7 was characterized by an initial focal cytopathologic effect at 100 hours that quickly progressed to involve the whole epithelium.¹³⁰ Frequently, the cilia of inclusion-bearing cells were noted to be intact. In contrast to the findings with adenovirus type 7, a type 12 strain resulted in only a mild cytopathologic effect on the organ culture system.¹³⁰

Microscopic examination of autopsy material from patients dying of adenoviral pneumonia revealed a loss of cilia in the tracheal epithelium, proliferation of other respiratory epithelial cells, and the presence of intranuclear inclusions.^{39,49,77,101,219,717,722,725,752} In severe pneumonia, total destruction along with necrotizing bronchitis, bronchiolitis, and pneumonia is observed (Fig. 156.1). Mononuclear cellular infiltration is seen, and hyaline membranes and necrosis are present. Cilia and goblet cells are absent, and muscle fiber bundles and elastic fibers are dispersed. Frequently, epithelial cells have a characteristic appearance with adenoviral infection. These infected cells are enlarged grossly and lose their nuclear membranes; the nuclear material has migrated into the cytoplasm.⁵⁴⁹ Blood vessels show edema, separation of filaments in their walls, and occasionally thrombosis.⁷⁵²

FIG. 156.1 The lung of a 17-month-old infant with adenoviral pneumonia. The infant died 10 days after the onset of illness, with no other contributing disease. The adenovirus isolated was not typed. A patchy pneumonia is present, and the arrow indicates two cells with nuclear inclusions. *Inset*, Two similar cells with typical adenoviral nuclear inclusions at higher magnification (hematoxylin and eosin staining, $\times 190$; inset, $\times 770$). (Courtesy Dr. David D. Porter, Department of Pathology, David Geffen School of Medicine at UCLA.)

In cases of pharyngoconjunctival fever, conjunctival biopsy specimens in volunteer studies revealed an inflammatory response with lymphocytic infiltration of the submucosal layer.^{42,43} Biopsy material from palatine tonsils of infected volunteers revealed hypertrophy and hyperplasia of the lymphoid tissue, with congestion and edema of the surrounding connective tissue.

On histologic examination, adenoviral inclusions are characterized by small eosinophilic and larger basophilic intranuclear bodies.^{39,219,499,629}

Hepatic involvement in adenoviral infection has been reported frequently.^{4,22,49,91,219,549,625} In addition to isolation of virus from the liver, focal areas of liver necrosis accompanied by characteristic hepatic intranuclear inclusions have been demonstrated.^{4,91,749} Electron microscopic examination has revealed adenoviral particles within the intranuclear inclusions.^{4,49,549,717,749} Hematogenous spread to the central nervous system (CNS) has been observed.⁶¹³ Most patients with adenoviral CNS infection have had an associated pneumonia.^{131,612} In CNS disease, the brain is edematous and congested. On microscopic examination, a perivascular accumulation of lymphocytes is noted, along with gigantic nuclear inclusions in the cortical neurons. Viral particles have been observed within these nuclear inclusions by electron microscopy.¹¹⁵

In epidemic keratoconjunctivitis caused by adenovirus type 8, the walls of the conjunctival vessels are damaged, and aneurysms are present. The surrounding conjunctival connective tissue is edematous. The virus has been suggested to penetrate the cornea along nerves deep into the epithelial layers in a manner similar to that occurring in herpes simplex virus (HSV) infection.⁶⁹⁰

Adenoviral strains have been isolated from and intranuclear inclusions have been demonstrated in renal tubular epithelium, lymph nodes, muscle, and gastrointestinal epithelium.^{46,91,714,746,747,749}

Immunologic Events

The local response in adenoviral infection depends on the site of viral inoculation, the method of transmission, the viral serotype, the concentration of inoculum, and the antibody status of the host. Three days after infection develops, when virus can be recovered from the nasopharynx, marked transudation of proteins from serum into the respiratory tract occurs, along with the production of secretory IgA antibody.⁴⁵⁷ Approximately 7 days after the onset of illness, serum-neutralizing, hemagglutination-inhibiting, and complement-fixing antibodies appear.^{140,408,551} At the same time, the nasal secretions contain specific IgA and IgG antibodies.⁴⁸ In general, neutralizing antibody is the most sensitive indicator of adenoviral infection, hemagglutination-inhibiting antibody is less sensitive, and complement-fixing antibody is

*References 17, 18, 49, 63, 77, 101, 253, 265, 269, 432, 450, 608.

the least sensitive.^{381,524} Antibody titers peak in 2 to 3 weeks; complement-fixing antibody declines in 2 to 3 months but may persist for up to a year.^{140,551} Neutralizing antibody persists for a longer period and is measurable in many instances for periods as long as 10 years. Reinfection with the same adenoviral serotype is rare because of type-specific immunity.^{43,584}

Although alterations in leukocytes are not common findings, a decrease in the number of lymphocytes has been observed before or at the onset of clinical illness and an increase in neutrophils early in the disease, followed by a decrease later. Neutropenia may develop in severe disseminated illness and is attributed to a direct toxic effect of virus on leukocytes, marrow reserves, or both.¹⁶³ The erythrocyte sedimentation rate (ESR) of children has been normal or elevated to 55 mm/h.^{633,632}

Studies by Ginsberg and associates²⁴⁷⁻²⁴⁹ in murine adenoviral pneumonia model systems noted that tumor necrosis factor- α , interleukin-1, and interleukin-6 were elaborated during the first 2 to 3 days of infection. However, only tumor necrosis factor- α played an early role in the initial phase of pathogenesis. The second phase of the inflammatory response is caused by the infiltration of cytotoxic T cells. In an extensive study, Kawasaki and colleagues³⁶² compared numerous clinical and laboratory test results in children with adenoviral infections with those in children with influenza and respiratory syncytial virus (RSV) infections. They found that the children with adenoviral infections had higher white blood cell (WBC) counts with a greater number of neutrophils than did children with influenza or RSV infections (12,322, 7638, and 8460 WBCs/mm³, respectively). The children with adenoviral infections also had more atypical lymphocytes and higher C-reactive protein (CRP) and ESR values. The mean serum interleukin-6 concentration was significantly higher in the children with adenoviral infections than it was in those with influenza and RSV infections (131.0, 26.7, and 15.0 pg/mL, respectively).

Mistchenko and coworkers⁴⁷¹ studied cytokines and adenovirus-specific circulating immune complexes in 38 children with adenoviral infections. They placed the patients into three groups based on the severity of their respiratory illnesses: moderate illness, severe illness, and fatal illness. Serum interleukin-1 was not detected in children with moderate illness but was found in 7 of 12 with severe illness and in 13 of the 16 children who died. Tumor necrosis factor- α frequently was present in the sera of fatal cases, it was not present in the sera of moderately ill children, and it was detected in the sera of only 2 of 12 patients with severe but nonfatal illness. Interleukin-8 was noted in all sera, but values were highest in children with fatal illness. Serum immune complexes (containing IgG) were found in 7 of the 16 children who died. Finally, patients with increased concentrations of interleukin-6, interleukin-8, and tumor necrosis factor- α were those with hypoperfusion, febrile peaks, seizures, and a manifestation of septic shock. Five of 10 children with severe or fatal illness had serum autoantibodies specific for smooth muscle.

Matsubara and associates⁴⁴⁹ noted the participation of peripheral blood CD8⁺ T cells and HLA-DR⁺, CD8⁺ T cells in children with adenoviral infection. One child with severe adenoviral type 7 pneumonia had a marked increase in HLA-DR⁺ CD8⁺ T cells, serum levels of interferon- γ , and peripheral blood interferon- γ -producing T cells.

CLINICAL MANIFESTATIONS

Adenoviral infections are exceedingly common events, and the spectrum of disease is quite broad (Table 156.3). As noted in Table 156.3, some specific adenoviral diseases exist; however, the overall majority of infections involve a variety of anatomically associated illnesses. In many instances, similar illnesses are caused by other respiratory viruses, and the clinical spectra of the various adenoviral serotypes frequently overlap. Certain specific adenoviral types do have clinical characteristics that facilitate etiologic diagnosis, however.

Respiratory Tract

Common Cold

Although adenoviruses frequently receive etiologic consideration in colds, they are, in fact, associated only rarely with this illness.³⁴⁵

In one report, 3% of common colds in children were attributed to adenovirus,⁵⁴¹ and in another study, 6.4% of children with coryza had adenoviral isolates.¹⁷⁶ Respiratory tract infections with adenoviruses usually are associated with fever and, frequently, with some degree of pharyngitis; therefore, when strict clinical criteria are applied, they do not qualify as colds.^{320,636} Occasionally, adenoviruses, particularly types 1, 2, 3, 5, and 7, have been recovered from patients with typical colds.

Nasopharyngitis, Pharyngitis, and Tonsillitis

Adenoviral pharyngitis is an acute illness characterized by fever, sore throat, extensive exudative tonsillitis, and frequently, cervical adenopathy.^{162,176,345,477,621} In two studies involving 74 children with adenoviral pharyngitis, Ruuskanen and associates⁵⁸⁹ described the pharyngeal findings. Most commonly, only mild inflammation and redness were observed. When exudates were present, they found them to be thick and membranous, thin and follicular, or thin and spotty; most typical were follicular and spotty exudates. Associated symptoms include malaise, headache, myalgia, chills, and cough. In infants and preschool children, nasal congestion and discharge are noticeable, and abdominal pain is a common complaint.⁶⁷⁶ Children with adenoviral acute febrile pharyngitis also frequently have laryngotracheitis, bronchitis, or pneumonia.⁷³⁸ The usual duration of illness varies from 5 to 7 days, although occasionally, symptoms persist well into the second week.⁵⁸⁹

Acute febrile pharyngitis is the most common adenoviral illness in children and is particularly important as an epidemic illness in closed environments.^{47,621,633,738} For example, in an epidemic in a children's home, 63% of the residents were infected with adenovirus type 7a.²⁸⁰ Moffet and colleagues⁴⁷⁷ noted that adenoviruses were the etiologic agents recovered most commonly from hospitalized preschool children with febrile exudative pharyngitis; 23% of the children studied had adenoviral infections. In a university student health service study, 2.4% of illnesses with acute febrile pharyngitis were caused by adenoviruses.⁴⁹¹ Adenoviruses account for 37% to 75% of cases of nonstreptococcal pharyngitis in military recruits.

In children, 86% of cases of febrile pharyngitis are associated with adenovirus types 1, 2, 3, 5, and 7.^{280,320,477}

On occasion, adenovirus types 7a, 9, 14, 15, and the intermediate strain 21/H21+35^{300,621,633} also have been noted in association with pharyngitis. In military recruits, adenovirus types 4 and 7 are the main etiologic agents.

Acute Respiratory Disease

ARD is an epidemic disease that occurs predominantly in military recruit populations. This illness was studied extensively during World War II by the Commission on Acute Respiratory Diseases, and although individual cases were quite undifferentiated, the epidemiologic aspects of the outbreaks clearly indicated a specific etiologic agent.^{31,122,246,621,639,675} The disease is an acute, febrile respiratory illness of short duration with constitutional and localized respiratory symptoms.¹⁹³ After an incubation period of 5 to 7 days, fever (mean temperature of 39.5°C), pharyngitis, laryngitis, tracheitis, and a nonproductive cough develop.^{59,138,246,533} The initial dry, hacking cough may progress to paroxysms. Malaise, myalgia, chills, headache, dizziness, rhinitis, conjunctivitis, abdominal pain, and local cervical lymphadenopathy are common complaints.¹³⁸ The inflammatory process may spread to the bronchi, the bronchioles, and the parenchyma of the lungs. In epidemics, as many as 67% of those affected wheeze and have other evidence of small airway obstruction; pneumonia occurs in 10% to 20%.^{303,412,483} The illness gradually resolves over the course of an 8- to 36-day period.²¹⁷ Early in the illness, the total WBC count may be slightly elevated, with a small increase in the percentage of polymorphonuclear leukocytes.

In experimental aerosol-induced ARD, the incubation period ranged between 6 and 13 days.¹²⁸ Typical illness included fever to 39°C, rhinitis, prostration, malaise, myalgia, and headache. Pneumonia occurred occasionally. The virus was recovered from throat culture specimens 5 days after inoculation, from the nose at 6 days, and after 9 days in fecal specimens. Serum-neutralizing antibody responses occurred between the third and fourth weeks. All ill volunteers had leukopenia and an elevated ESR during the illness.

TABLE 156.3 Clinical Spectrum of Adenoviral Infections

System/Organ	Illness Category	Epidemic Occurrence	Frequency	Adenoviral Type(s)
Respiratory	Common cold	No	Rare	1, 2, 3, 5, 7
	Nasopharyngitis, pharyngitis, and tonsillitis	Yes	Common	1, ^a 2, ^a 3, ^a 4, 5, ^a 7, ^a 7a, 14, 15, (21/H21+35) ^b
	Acute respiratory disease	Yes (in military recruits)	Very common	2, 3, 4, ^a 5, 7, ^a 8, 11, 14, 21
	Acute laryngotracheitis	No	Occasional	1, 2, 3, 5, 6, 7
	Acute bronchiolitis	No	Occasional	3, 7, 21, 60
	Pneumonia (civilian population)	Yes	Common	1, 2, 3, ^a 4, 5, 7, ^a 7a, ^a 8, 11, 14, 14p1, 21, ^a (21/H21+35), ^b 35, 55, 56
	Atypical pneumonia in military recruits	Yes	Common	4, ^a 7, ^a 14, 21
	Pertussis-like syndrome	No	Rare	1, 2, 3, 5, 12, 19
	Bronchiolitis obliterans	No	Rare	2, 3, 7, 21
	Unilateral hyperlucent lung	No	Rare	7, 21
Eye	Acute follicular conjunctivitis	Yes	Common	1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 15, 16, 17, 19, 20, 22, 31, 34, 37
	Pharyngoconjunctival fever	Yes	Common	1, 2, ^a 3, ^a 4, ^a 5, 6, 7, ^a 7a, ^a 8, 14, ^a 37
	Epidemic keratoconjunctivitis	Yes	Occasional	2, 3, 4, 5, 7, 8, ^a 10, 11, 13, 14, 15, 16, 17, 19, 23, 29, 37, 54, 56
Skin	Morbilliform and rubelliform exanthem	Rare	Occasional	3, 4, 7, 7a
	Roseola-like	No	Occasional	1, 2
	Stevens-Johnson syndrome	No	Rare	7
	Petechial exanthem	No	Rare	7
Genitourinary	Acute hemorrhagic cystitis	No	Rare	7, 11, 21
	Nephritis	No	Rare	3, 4, 7a
	Orchitis	No	Rare	Unknown
	Oculogenital syndrome	Yes	Rare	19, 37
Gastrointestinal	Gastroenteritis	Yes	Common	1, 2, 3, ^a 5, 7, ^a 11, 12, 15, 17, 31, ^a 32, 33, 40, ^a 41 ^a
	Mesenteric lymphadenitis	No	Rare	1, 2, 3, 5, 7
	Intussusception	No	Rare	1, 2, 3, 5, 6, 7
	Appendicitis	No	Rare	1, 2, 7
	Hepatitis	No	Rare	1, 2, 3, 5, ^a 7, (11+35/H11+35) ^b
Heart	Myocarditis	No	Rare	3, 7, 7a, 21
	Pericarditis	No	Rare	7
Neurologic	Encephalitis and meningitis	No	Rare	1, 2, 3, 4, 5, 6, 7, 11, 12, 26, 32, 41
	Transient encephalopathy	No	Rare	3
	Acute flaccid paralysis	Yes	Rare	21
Joint	Arthritis	No	Rare	7
Auditory	Deafness	No	Rare	3
Endocrine	Thyroiditis	No	Rare	Unknown

^aMost common.^bIntermediate strain.

The syndrome occurs most commonly in military recruits early in basic training; illness has been documented in as many as 90% of new trainees within the first 8 weeks of arrival at a training site.³⁰³ The usual etiologic agents are adenovirus types 4 and 7. Occasionally, epidemics have been associated with adenovirus types 3, 11, 14, and 21,^{75,214,650,693} and sporadic cases have been noted in connection with adenovirus types 2, 5, and 8.^{303,533} The peak seasons of illness are winter and spring.³⁰³

Because of the magnitude of the problem of ARD in military recruits, live attenuated adenoviral vaccines against types 4 and 7 were developed and used in all branches of the U.S. military beginning in the early 1970s.^{35,261} These vaccines were used successfully until the early 1990s, when production delays occurred; subsequently, in 1995, the vaccine manufacturer stopped production. From 1999 to 2011, no vaccine was available, and epidemic disease returned to military training bases.^{75,384,587,590,650,693} Although illness may occur in civilian adults, it is an uncommon event and not epidemic. In volunteer studies, subjects with serum antibody to a particular adenoviral type are protected against disease with that type of adenovirus induced by intranasal inoculation.^{43,128}

Epidemic ARD has not been described in children. However, a sporadic comparative illness, usually clinically identified as acute

bronchitis, is commonly the result of adenoviral infection.⁷⁴¹ Adenovirus type 7 is the etiologic agent most frequently found in these cases.

Acute Laryngotracheitis

On occasion, adenoviruses have been implicated as a cause of acute laryngotracheitis. In general, the croup caused by adenoviruses is not severe and often is manifested only as a barking, brassy cough. Laryngotracheitis frequently is seen in association with febrile pharyngitis, bronchiolitis, and pneumonia.⁶⁶⁹ Epidemics have not been observed. Adenovirus types 1, 2, 3, 5, 6, and 7 have been implicated as etiologic agents.

Acute Bronchiolitis

Adenoviruses account for approximately 5% to 18% of cases of bronchiolitis in infants.^{233,722} In a recent study of 143 children with adenoviral infections, the admitting diagnosis was bronchiolitis in 24%.⁵⁷⁴ The bronchiolitis caused by adenoviral infection is sporadic and usually similar to illness associated with other viral agents. Occasionally, adenoviral bronchiolitis occurring early in infancy has been fatal or has resulted in serious residual lung damage and chronic disease.⁷¹¹ This severe illness has been associated with serotypes 3, 7, and 21.

Pneumonia

Young children. Adenoviruses are common isolates in children with pneumonia. The overall frequency of adenoviruses as a cause of nonbacterial pneumonia in children is less than that of RSV and parainfluenza virus type 3, but an alarming number of fatal illnesses have been noted. Severe and fatal illnesses in infants and young children have occurred in association with adenovirus types 1, 2, 3, 4, 5, 7, 7a, 7h, 7i, 8, 19, 21, 35, and the intermediate strain 21/H21+35.* The more severe cases of pneumonia have been linked to types 3, 7, 14, 21, and 55.^{86,242,250,435,614,649,725} Adenoviral pneumonia has been epidemic and sporadic.^{94,101,112,182,415}

Severe pneumonia occurs most commonly in neonates and young children aged 3 to 18 months.[†] The onset of illness is acute, with persistent cough and fever (>39°C). On physical examination, moderate to severe dyspnea is apparent, as is the associated tachypnea. Inspiratory and expiratory wheezes and rales are heard on auscultation. Other signs and symptoms include lethargy, diarrhea and vomiting, pharyngitis, and occasionally, conjunctivitis. Extrapulmonary complications that occur commonly are meningitis, encephalitis, seizures, splenomegaly, hepatomegaly and hepatitis, myocarditis, nephritis, bleeding tendency, and exanthems.^{49,77,101,124,397,612,614,629,632} Chest radiographs reveal diffuse infiltrates, which usually are bilateral and may be bronchial, peribronchial, or interstitial.^{39,397,574,718} Hyperinflation and lobar collapse occur frequently.²⁵³ Rarely, pleural effusions or mediastinal lymphadenopathy has been described.³⁹⁷ In surviving infants, symptoms persist for 2 to 4 weeks, and radiographic changes resolve slowly, frequently being present at the 3-week follow-up examination.^{101,112,614} Recovery often is gradual, and exacerbations occur commonly.^{331,531}

Serious sequelae often result from adenoviral lower respiratory disease, particularly in association with adenovirus types 3, 7, 7a, 21, and 21a.^{28,40,93,190,253,271,331,397,614} Such sequelae include bronchiectasis, bronchiolitis obliterans, and unilateral hyperlucent lung.[‡] An estimated 14% to 60% of children with documented adenoviral lower respiratory tract disease have some degree of permanent pulmonary sequelae.^{253,397,613,614} In a study of 27 children conducted 10 years after they had documented adenoviral type 7 pneumonia, 12 had radiographic evidence of bronchiectasis or residual pulmonary changes; 16 children had abnormal results on pulmonary function studies.⁶¹³

Hakansson and coworkers²⁷² previously demonstrated increased binding of adherent *Streptococcus pneumoniae* to cultured human respiratory tract epithelial A549 cells in the presence of infection with adenovirus types 1, 2, 3, and 5, thereby postulating that adenovirus infection upregulated receptors for *Streptococcus pneumoniae*. Lebel and colleagues⁴⁰⁴ subsequently reported 7 cases of adenoviral infection with secondary bacteremia in hospitalized children over an 8-year period, the majority (6 of 7) being immunocompetent and previously healthy. They highlighted the importance of considering secondary bacteremia as a possible complication of adenoviral infection in immunocompetent children.

Macek and associates⁴³⁶ have suggested that persistent adenoviral infection may be the cause of chronic obstructive airway disease in children. They noted adenoviral antigen in bronchoalveolar lavage specimens from 31 of 34 patients with chronic disease but in no bronchoalveolar specimens from a control group. Wurzel and colleagues⁷³⁰ performed adenovirus genotyping on bronchoalveolar lavage fluid samples of 245 children found to have protracted bacterial bronchitis and mild bronchiectasis (evidence of chronic endobronchial suppuration). Species C adenoviruses were the most common viruses detected comprising 23 of 24 adenovirus-positive lavage specimens.

On occasion, severe and fatal adenoviral pneumonia has been related to malnutrition, environmental crowding, or a preceding severe viral disease such as measles.^{28,40,39,253,393,499,614}

Severe adenoviral pneumonia associated with adenovirus types 3 and 7 also has been reported occasionally in previously healthy adults.^{537,548,619} One adult had severe pneumonia caused by adenovirus

type 21 that was associated with myalgia, rhabdomyolysis, and myoglobinuria.⁷²⁶ Hage and colleagues²⁷¹ reported on six cases of severe pneumonia between 2005 and 2013 in Germany due to human adenovirus type 21a, the difference from adenovirus type 21 being a unique 15-amino acid sequence deletion and a 2-amino acid sequence in the RGD loop resembling the RGD loop of adenovirus types 3 and 7.

Atypical pneumonia in military recruits. Approximately 7% to 20% of cases of pneumonia in military recruits are associated with adenoviral infection.^{80,210,239} Primary atypical adenoviral pneumonia commonly occurs in the winter months and generally is caused by adenovirus types 4, 7, and 21.²¹⁰ The illness is associated with fever, cough, sore throat, rhinorrhea, and chest pain. Other common symptoms include nausea, vomiting, myalgia, headache, and diarrhea. On physical examination, rales and pharyngitis are present in almost all cases. Rhinitis and generalized lymphadenopathy are observed in approximately half of those afflicted, and occasionally conjunctivitis is noted. Chest radiographs reveal a bilaterally mottled appearance, most prominent in the lower lobes; they remain abnormal for 4 to 36 days.⁸⁰ Although serum cold agglutinins are observed, titers of 1:32 or higher are detected in only 18% of patients.^{80,239}

Fatal pneumonia, absolute leukopenia, and disseminated disease have been reported in four previously healthy military trainees. Adenovirus type 7 was the etiologic agent in three of these cases, and the fourth illness was caused by adenovirus type 4.^{169,412}

Pertussis-like syndrome. A pertussis-like illness has been noted in association with several adenoviruses, including types 1, 2, 3, 5, 12, and 19.^{121,123,280,503,516} The illness occurs commonly in children younger than 36 months. The onset of illness is insidious and initially suggestive of a cold. The cough becomes progressively worse and, by 1 to 2 weeks, is paroxysmal. Severe recurrent episodes of paroxysms result in the production of mucus, posttussive fatigue, and vomiting.¹²³ Approximately 50% of children have a typical whoop, and cyanosis occurs with the paroxysms. Peripheral leukocytosis with WBC counts ranging from 25,000 to 125,000 cells/mm³, along with lymphocytosis and thrombocytosis, is the usual finding.^{121,516} The recovery time ranges from 4 to 10 weeks from the onset of illness.¹²³ Radiologic evidence of bronchiolitis is present in most children; interstitial pneumonia occurs occasionally. In our opinion most, and probably all, of these pertussis-like illnesses are indeed *Bordetella pertussis* infections in which adenovirus is a coinfecting agent (see Chapter 129). In young infants, coinfection (adenovirus plus *B. pertussis*) may lead to more severe disease.^{41,414,453}

Bronchiolitis obliterans. Bronchiolitis obliterans is a chronic bronchiolitis that initially was described in 1901 by Lange.³⁹⁸ It has been noted to occur after measles, influenza, and pertussis, as well as after the inhalation of toxic substances.^{28,40,722} Adenovirus types 2, 3, 7, and 21 have resulted in a bronchiolitis obliterans-type chronic illness.^{6,28,40,93,474,544,711,722} These adenoviruses cause a severe necrotizing bronchiolitis that heals with fibrosis and predominantly obliterates the small airways.³⁵ The onset of disease is characterized by an acute febrile illness, cough, and respiratory distress. Disease may wax and wane for several weeks or months and is associated with recurrent episodes of atelectasis, pneumonia, and wheezing. Although some children recover from these episodes, the remainder have chronic pulmonary disease, including irreversible atelectasis, bronchiectasis, or hyperlucent lung syndrome.^{40,711,722}

Castro-Rodriguez and colleagues⁹³ conducted a 5-year follow-up study of 38 children hospitalized with adenoviral pneumonia during an outbreak in Santiago, Chile, in 1998. Bronchiolitis obliterans developed in almost 50% of these children. Nosocomial acquisition of adenoviral infection was found to be associated more significantly with the development of bronchiolitis obliterans than community-acquired infection was. Murtagh and colleagues conducted a retrospective review of 415 children with lower respiratory infection caused by adenoviruses. They found that risk factors for the development of bronchiolitis obliterans included prolonged hospitalization (>30 days), multifocal pneumonia, and hypercapnia.⁴⁹⁰ Wu and colleagues⁷²⁸ identified hypoxemia as an independent predictor of bronchiolitis obliterans in a retrospective study of 544 hospitalized children with acute respiratory infection due to adenovirus in China.

Unilateral hyperlucent lung. Unilateral hyperlucent lung is a well-defined syndrome characterized by increased translucency of all or part of one

*References 17, 39, 40, 49, 77, 78, 101, 112, 146, 153, 232, 253, 305, 331, 352, 353, 374, 375, 377, 393, 401, 432, 450, 474, 475, 488, 512, 531, 544, 545, 565, 612, 614, 629, 632, 725.

lung, along with a reduction in lung size.^{133,437} The unilateral hyperlucency is associated with a decrease in the size and number of pulmonary vessels, as observed on pulmonary angiograms, and an absence of peripheral filling at bronchography.⁴³⁷ Although the disease may have a number of causes, including pneumonia secondary to other viruses, it has been noted to occur after severe necrotizing bronchiolitis and pneumonia caused by adenovirus types 7 and 21.^{437,722}

Eye

Acute Follicular Conjunctivitis

Acute follicular conjunctivitis is the most common and benign of the adenoviral infections of the eye. The infection in this disease is confined to the eye, generally is unilateral, and is manifested by follicular lesions on the palpebral conjunctival surface. Symptoms occur after an incubation period of 5 to 7 days and include lacrimation, itching, burning, a foreign body sensation, and conjunctival erythema.¹⁵⁰ It should be noted that, although the preceding symptoms increase the likelihood of viral infection, rather than bacteria, the diagnosis by clinical symptoms alone can be difficult to make. Examination shows erythema and lymphoid follicular hyperplasia in the conjunctiva in association with serous drainage and increased lacrimation. Occasionally, adenopathy of the preauricular lymph nodes is seen. Symptoms resolve in 10 days to 3 weeks, with recovery usually complete.^{127,150} Adenovirus types 1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 15, 16, 17, 19, 20, 22, 30, 31, 34, and 37 have been isolated from the eyes of afflicted patients.^{64,124,150,190,443,597,604,668}

Pharyngoconjunctival Fever

By definition, pharyngoconjunctival fever is a syndrome characterized by fever, pharyngitis, and conjunctivitis. During epidemics, not all patients have the complete syndrome triad. For purposes of this discussion, all descriptions of frequency of signs and symptoms are calculated from the starting point of 100% fever, pharyngitis, and conjunctivitis.

Tables 156.4 and 156.5 summarize the frequencies of specific symptoms and signs.* The usual onset of illness is abrupt, with sore throat, generalized aches and pains, eye irritation or pain, and fever. Throat complaints vary from mild to severe. On examination, the tonsils and pharyngeal lymphoid tissue are hypertrophied with pharyngeal redness varying considerably from patient to patient. Approximately one-third of affected patients have follicular exudative lesions that cannot be differentiated from streptococcal disease on clinical grounds. Hypertrophy of the adenoids occurs, which may result in nasal blockage. Coryza and posterior nasal discharge are common, leading to cough in many instances.

With respect to conjunctivitis, most patients note some aching or soreness; photophobia and lacrimation are unusual. The appearance of the palpebral conjunctiva usually is granular. The lesions may be almost microscopic or 2 to 3 mm in diameter. Hemorrhages occasionally are noted on the bulbar surface. Frequently, involvement starts in one eye and does not involve the other eye until 2 or 3 days later. Occasionally, the involvement is restricted to one eye.

Compared with other respiratory viral infections, the duration of illness with pharyngoconjunctival fever is long. In most patients, the fever is sustained or remittent for 3 to 4 days. However, approximately 10% of patients have fever that lasts longer than 7 days. Throat and eye findings usually are improved considerably by the seventh day of illness, but these findings and nasal complaints, fatigue, and headache may persist for 14 days.

In epidemic pharyngoconjunctival fever, the most likely etiologic agent is adenovirus type 3.[†] The next most prevalent adenovirus associated with epidemic disease is type 7.^{85,172,209,735} One or more epidemics also have been noted with adenoviruses 2, 4, 7a, 11, and 14.^{11,16,43,135,177,180,500,680,741} Sporadic occurrences of pharyngoconjunctival

fever have been observed in association with infections with adenoviruses 1, 2, 3, 4, 5, 6, 7, 7a, 8, 14, 19, and 13/30 (an intermediate type).*

Epidemic Keratoconjunctivitis

Epidemic keratoconjunctivitis is caused most commonly by adenovirus type 8, but it also has resulted from infection with adenovirus types 2, 3, 4, 5, 7, 10, 11, 13, 14, 15, 16, 17, 19, 22, 23, 29, 37, 53, 54, and 56.¹ Currently, adenovirus type 37 is the virus most commonly recovered from patients with epidemic keratoconjunctivitis in the United States and Europe. The most severe disease is associated with adenovirus types 5, 8, and 19.¹³⁷ More recently in Japan, adenovirus 54 and 56 have been recovered from patients with epidemic keratoconjunctivitis.^{10,326}

The illness occurs most commonly in adults, but a few cases have been reported in children.^{281,476,647} It has no seasonal pattern. Although transmission of the viral agent from the respiratory tract to the eye occurs in sporadic cases, the usual method of viral spread is by contaminated ophthalmic instruments and eye solutions, hand-to-eye contact by medical personnel and others, swimming pools, or hands or fomites in close-contact situations, such as in families and in industry.⁴ The incubation period typically is 5 to 10 days but ranges from as short a period as 2 days to as long as 2 weeks.^{139,381} The initial symptom generally is unilateral, acute, follicular conjunctivitis that suggests the presence of a foreign body. Photophobia, lacrimation, discharge, hyperemia, and edema of the conjunctiva are notable. Preauricular adenopathy occurs in as many as 90% of patients, and 50% of those afflicted have pharyngitis and rhinitis. Spread to the other eye may occur in 2 to 7 days. Seven to 10 days after onset of the disease, the conjunctivitis resolves, and painful, superficial, punctate epithelial opacities appear in the center of the cornea. These lesions frequently extend subepithelially and then heal, with subepithelial infiltrates left behind that may persist for months. In severe cases, hazy vision may continue for several years.³³

An infantile form of epidemic keratoconjunctivitis has been described that usually affects children younger than 2 years old.¹⁸¹ This pseudomembranous or membranous conjunctivitis generally is accompanied by high fever, pharyngitis, otitis media, diarrhea, and vomiting. Preauricular lymphadenopathy typically is absent.⁶⁴⁷

Virus can be recovered from the eye for a usual period of approximately 2 weeks but has been detected for 2 to 3 years in patients with chronic papillary conjunctivitis.^{137,543} In acute illness, conjunctival scrapings obtained during the first 10 days of infection reveal characteristic inclusion bodies when stained with Giemsa.²⁹¹ Virus-specific fluorescent antibody staining is diagnostic in epidemic keratoconjunctivitis.⁶⁰² Preparations of corneal and conjunctival epithelia reveal adenoviral particles when examined with the electron microscope.¹⁴⁴

Skin

Adenovirus types 1, 2, 3, 4, 7, and 7a, plus several unknown types, have been noted in connection with exanthematous disease.¹⁰⁶ The cutaneous manifestation most commonly associated with adenoviral infection is an erythematous maculopapular rash that appears while the child is febrile. In many instances, children with this illness have been thought to have either measles or rubella.³⁹³ In most adenoviral infections with exanthems, other clinical findings more characteristic of adenoviruses, such as conjunctivitis, rhinitis, pharyngitis, and lymphadenopathy, also are present. In some instances, the exanthem truly is morbilliform with a characteristic confluence, but Koplik spots do not occur.

A widespread erythematous rash often is present early in the course of severe pneumonia in infants.²⁵³ Chany and colleagues¹⁰¹ noted a measles-like rash in five patients who died of adenovirus type 7a pneumonia. One report describes a child with an adenovirus type 7 infection and illness suggestive of meningococcemia.⁵⁹² This patient had fever, vomiting, diarrhea, and a petechial exanthem. Rocholl and associates⁵⁷⁴ noted that rash occurred in 10 percent of 143 adenoviral illnesses in children.

On several occasions, illness characterized by fever and defervescence and then the appearance of a maculopapular rash suggesting the diagnosis of roseola infantum has been observed.^{208,222,333,334,504} Adenoviral infections also are confused with rubella. However, the respiratory symptoms and the degree of fever associated with adenoviral infection should clarify the diagnosis. With rubella, respiratory complaints and fever are minimal. On occasion, severe disease with Stevens-Johnson syndrome has been noted. Such patients frequently have pneumonia, and the illness is quite similar to that caused by *Mycoplasma pneumoniae*.

Lähdeaho and associates³⁹⁶ have noted that serum antibodies to the E1b protein-derived peptides of the enteric adenovirus type 40 are associated with dermatitis herpetiformis. Keyes and coworkers³⁷⁰ reported a case of a woman who underwent T-cell-depleted peripheral blood hematopoietic stem cell transplant that was complicated by EBV-associated posttransplant lymphoproliferative disorder and disseminated adenovirus infection. She underwent skin punch biopsy for a pruritic, burning rash described as 2- to 3-mm erythematous papules on the palms, some having a vesicle-like appearance, which, on closer inspection, revealed a firm keratotic plug. Biopsy demonstrated epidermal hyperplasia with a column of parakeratosis. Underlying and adjacent keratinocytes had focal acantholytic dyskeratosis with several keratinocytes having hyperchromatic nuclei. Mild interface dermatitis was also present. Immunohistochemical staining of the hyperchromatic nuclei was positive for adenovirus.

Genitourinary Tract

Acute Hemorrhagic Cystitis

Acute hemorrhagic cystitis is an uncommon manifestation of adenoviral infection in immunocompetent children and is characterized by a sudden onset of dysuria and frequency, with hematuria developing 12 to 24 hours later.^{403,407,441,484,485,510} Occasionally, fever, suprapubic pain, and enuresis occur. Antecedent upper respiratory tract infection is noted in some children. Symptoms persist for a few days to 2 weeks, with the usual duration being approximately 5 days. Acute hemorrhagic cystitis has been reported in both the United States and Japan. It occurs primarily in children, most often boys, and usually is associated with adenovirus type 11. Occasionally, adenovirus types 7 and 21 have been implicated. Adenoviral antigen has been identified by immunofluorescence in exfoliated bladder cells. Although no sequelae have been reported, the long-term prognosis is unknown.⁴⁸⁴ Montaruli and colleagues⁴⁷⁸ reported the case of a 14-year-old boy who underwent allogeneic bone marrow transplantation for refractory acute lymphoblastic leukemia. He developed acute hemorrhagic cystitis 4 weeks after transplant, complicated by adenovirus-induced obstructive uropathy and acute renal failure. The child eventually recovered but required temporary placement of a double J stent in order to relieve the obstruction.

Nephritis

Hematuria occasionally has been reported in infants with severe pneumonia and disseminated adenoviral infection. Red blood cells and, at times, red blood cell casts also have been noted in the urine of some children with upper respiratory illnesses caused by adenoviruses and specifically in patients with pharyngoconjunctival fever associated with adenovirus types 3, 4, and 7a.^{621,630,676,680} In one instance, a young boy had a maculopapular and petechial exanthem and thrombocytopenia associated with adenovirus type 7 infection. Hematuria also was present.

Orchitis

Orchitis developed in one child who had a 5-day history of pain and fever, erythema, and swelling of the right testicle.⁵⁰² The testicular involvement resolved in several days, and the illness was associated with a 16-fold rise in adenoviral complement-fixation antibody titer.

Oculogenital Syndrome

In 1977, Laverty and associates⁴⁰³ reported a woman who, in addition to pharyngoconjunctival fever, had cervicitis and paresthesia of the legs; a type 19 adenovirus was recovered from this woman's cervix. In Perth, Australia, adenovirus type 19 was recovered from the genital tracts of 59 men and women being examined for genital HSV infection in a clinic for sexually transmitted diseases.³²⁵ Several of the patients also

³References 33, 83, 97, 137, 139, 142, 207, 335, 381, 447, 476, 479, 647, 709.

had conjunctivitis, and in two, adenovirus type 19 was isolated from conjunctival specimens. Similar oculogenital illnesses have been noted in association with adenoviral types 2, 8, and 37.^{96,597,642}

Hemolytic-Uremic Syndrome

Two 2-year-old children with hemolytic-uremic syndrome in association with adenoviral infections have been described.⁵⁸

Hemorrhagic Fever With Renal Syndrome

A 22-year-old woman with an adenovirus type 11 infection and hemorrhagic fever with renal syndrome has been reported.⁶⁷¹

Gastrointestinal Tract

Gastroenteritis

Infantile diarrhea has been associated with epidemic and sporadic adenoviral diseases such as acute upper respiratory tract infection, severe pneumonia, and pharyngoconjunctival fever.^{208,397,621,634,714} Outbreaks of diarrhea characterized by acute abdominal pain followed by diarrhea, nausea and vomiting, fever, headache, and pharyngitis have been associated with adenovirus type 3 and 7 infections.^{235,633} Other symptoms occurring in patients with diarrhea include conjunctivitis, rhinitis, pharyngotonsillitis, hepatomegaly, and cervical adenitis.⁶³⁴ In two patients who had diarrhea and upper respiratory illness in association with adenovirus type 15 infection, viral particles were visualized within the nuclei of mucosal cells at autopsy by electron microscopy.¹⁷⁰

The widespread use of electron microscopy for the study of rotaviral diarrhea led to the finding of previously unrecognized adenoviruses that were fastidious and could not be grown in routine cell cultures.^{182,601} These adenoviruses, now identified as types 40 and 41, subsequently were shown to be important causes of gastroenteritis in children.* In enteric adenoviral infection, diarrhea is the most prominent symptom.⁶⁶⁸ In children with adenovirus type 40 infection, Uhnoo and colleagues⁶⁶⁹ found that the mean duration was 8.6 days, as opposed to 12.2 days in those infected with adenovirus type 41. Most illnesses occur in children younger than 3 years old: the mean age for adenovirus type 40 diarrhea was 15.2 months, whereas it was 28.3 months in type 41 illnesses. Most patients had mild vomiting that lasted approximately 2 days. When compared with illnesses caused by established respiratory adenoviruses, fever occurred less commonly, was less severe, and had a shorter duration in enteric adenoviral infections. Upper respiratory symptoms and signs, such as pharyngitis, coryza, cough, and otitis media, were observed in 21% of children with enteric adenoviral infection. Brandt and colleagues⁷¹ noted that dual infections with respiratory viruses (such as RSV and enteric adenoviruses) are common occurrences, so caution should be observed in attributing respiratory symptoms to enteric adenoviruses. Chhabra and colleagues¹⁰⁹ conducted active population-based surveillance of 782 children under 5 years of age presenting with acute gastroenteritis to hospitals, emergency departments, and primary care clinics as compared to 499 healthy controls in Ohio, New York, and Tennessee. Adenovirus was detected in 11.8% of children with gastroenteritis versus 1.8% of healthy controls. Coinfection was seen in 13.1% of specimens, with *Norovirus* being the most frequently associated virus.

Yolken and Franklin⁷⁴³ found that enteric adenoviruses were an important cause of nosocomial diarrhea in infants who had previously undergone gastrointestinal surgery for necrotizing enterocolitis. Stockmann and colleagues⁶³⁵ evaluated stool pathogens via multiplex PCR assay among 779 children with 1089 diarrheal episodes. Adenovirus types 40 and 41 were the second most commonly detected virus, with 6% detected in hospitalized patients, 5% detected in the outpatient setting, and 10% detected in the emergency department. Liu and coworkers⁴²⁴ reanalyzed data from the Global Enteric Multicenter Study of moderate to severe diarrhea in children younger than 5 years in Africa and Asia. Not surprisingly, they found a greater pathogen incidence using molecular techniques for diagnosis (5 times the originally reported incidence). The attributable incidence of adenovirus 40/41 infection in infants was 3.9 episodes per 100 child-years and 1.8 episodes per 100 child-years in toddlers. Mhaisien and colleagues⁴⁶⁷ conducted a

study of 114 episodes of diarrheal illness in 93 pediatric oncology patients. Ninety-five percent of patients had one or more enteropathogens with adenovirus identified among 15% of patients. They found that patients with more than one pathogen had a longer duration of illness and greater likelihood of dehydration.

Mesenteric Lymphadenitis

Adenoviral serotypes 1, 2, 3, 5, and 7 have been recovered from lymph nodes and the appendix in cases of mesenteric lymphadenitis.^{46,63,379} Patients with mesenteric lymphadenitis often have abdominal pain and other symptoms similar to those of acute appendicitis. Pharyngitis is a frequently related finding. Mesenteric adenitis often is associated with concurrent or recent adenoviral illness.^{124,555} Frequently, the peak incidence of mesenteric lymphadenitis occurs when adenoviral illness is common in the community.

Intussusception

The suggestion that adenoviruses could be an etiologic factor in intussusception arose because these agents frequently can be recovered from throat, stool, and mesenteric lymph node specimens obtained from children who undergo surgery for intussusception.* Most children with intussusception were younger than 2 years old; some had preceding respiratory symptoms.^{582,746} Adenovirus serotypes 1, 2, 3, 5, 6, and 7 have been implicated. Typical adenoviral intranuclear inclusions have been demonstrated in cells in stool, intestinal epithelia (ileum), and the appendix by electron microscopy.^{511,746,747} Mesenteric lymph nodes often are enlarged at surgery.⁵²³ Increases in antibody titer to adenoviruses have been observed in children after the development of intussusception. Ukrapol and coworkers⁶⁷⁰ conducted a prospective cohort study of patients with intussusception using patients with acute gastroenteritis as controls. Viral infection was identified in 16 of 40 cases of intussusception seen over a 2-year period. Of the 16 cases where viral infection was implicated, adenovirus subtype C infection was identified in 12 cases (30%). They found that adenovirus infection was higher in the intussusception group as compared to the acute gastroenteritis group, which was statistically significant. Investigators have suggested that bowel wall hypermotility caused by direct viral involvement or by hypertrophy of lymphatic tissue is the lead point for the intussusception.^{46,119,234,511,552,582,746,747}

Appendicitis

Adenoviruses have been associated with both acute and chronic appendicitis.⁶³ Right iliac fossa abdominal pain in conjunction with sore throat is a common finding. The virus has been isolated from the appendix and mesenteric lymph nodes at surgery. During acute infection, lymphoid follicles of the ileum, appendix, and mesenteric lymph nodes are infected with virus. In chronic infection, adenovirus remains in cells; on microscopic examination, slight inflammation is seen in the appendix.

Hepatitis

Hepatitis in association with adenoviral infection has been reported many times in small infants, in children with overwhelming disseminated disease, and in immunocompromised patients.^{4,22,49,77,91,375,749} In one study, 27 of 30 persons thought to have sporadic infectious hepatitis were found to be infected with adenovirus type 5.²⁸² Adenovirus types 1, 2, and 3 were isolated from the stool specimens of 12 children younger than 3 years old in an outbreak of infectious hepatitis on a Native American reservation in Arizona.²⁸⁴

In one report, three children with severe, fatal adenovirus type 7 pneumonia had associated findings that simulated Reye syndrome: lethargy, diarrhea, seizures, elevated CSF pressure, myocarditis, hepatitis, and disseminated intravascular coagulation.³⁹⁵ Edwards and colleagues¹⁷⁵ reported three children with Reye syndrome and adenoviral infection. They suggested that adenoviruses might be an important agent in initiating the syndrome. Few cases of adenovirus hepatitis in immunocompetent pediatric patients have been reported, with two reports of death due to fulminant hepatic failure, one with associated encephalopathy.^{488,538,574}

*References 72, 76, 116, 154, 155, 254, 389, 391, 472, 514, 524, 575, 655, 669, 673.

*References 46, 52, 119, 234, 317, 511, 548, 582, 746, 747.

Matoq and Salahuddin⁴⁴⁸ reported the case of a previously healthy immunocompetent 23-month-old who developed acute noncholestatic hepatitis, hypoalbuminemia, anasarca, and pancytopenia associated with adenovirus infection and who eventually improved with supportive care. Ronan and colleagues⁵⁷⁸ conducted a review of 89 cases of adenovirus hepatitis among transplant recipients reported in the English literature from 1960 to 2012. They noted that 90% of infections occurred within 6 months after transplant, with 47% of infections occurring within the first month after transplant. Biopsy-confirmed histologic findings included hepatic necrosis (94%), intranuclear inclusions (72%), and smudge cells (21%). They highlighted the potential for the development of fatal fulminant hepatic failure due to adenovirus in solid organ transplant recipients that mimics that of fulminant hepatic disease due to herpes simplex virus infection. Kawashima and colleagues³⁶³ noted that elevation of γ -glutamyltransferase (GGT) without any specified causes preceded adenoviral hepatitis by 2 weeks in their case review, concluding that GGT may be a useful sentinel marker for adenoviral hepatitis. Van Montfrans and coworkers⁶⁸³ postulated that intestinal viral infection prior to transplant was a predictor for the development of acute intestinal graft-versus-host disease in 48 patients undergoing allogeneic hematopoietic stem cell transplantation. Among 15 of 48 patients with viruses detected in stool by PCR, 60% of cases had adenovirus infections.

Heart

Myocarditis

In children, myocarditis has been noted in association with severe pneumonia and disseminated disease caused by adenovirus types 7, 7a, and 21.^{287,292} Similar cardiac involvement has been seen in military recruits with severe ARD.^{101,112,287,621} One case of sudden death in an 11-year-old boy due to myocarditis with adenovirus type 3 has been documented.⁶⁶¹

The use of polymerase chain reaction (PCR) assays has led to recognition of adenovirus as the cause of many cases of acute myocarditis.^{65,73,267,433,445} In an extensive study of myocarditis and dilated cardiomyopathy, Bowles and coworkers⁶⁵ analyzed 773 endomyocardial biopsy samples obtained from patients of all ages. In this large group, 624 patients had myocarditis, and adenoviral DNA was identified by PCR in 142 (23%) of the endomyocardial biopsy samples. There were 26 neonates, 37 infants, 20 toddlers, 25 older children, 11 adolescents, and 23 adults. The results of this study suggest that adenoviruses are the leading viral cause of myocarditis, with enteroviruses being the second most common association (14%). On histopathologic examination, only 57 (40%) of the enterovirus-positive samples were found to be acute myocarditis. Simpson and colleagues⁶¹⁵ conducted a multicenter study of 21 pediatric patients with clinical myocarditis looking for detectable blood viral PCR within 6 weeks of symptom onset. They noted that 89% of positive blood viral PCRs were found in infants 12 months and younger with clinical myocarditis versus 3.5% of control patients. Nine patients had detectable viral PCR with one due to adenovirus (~11%).

Dilated Cardiomyopathy

In the study by Bowles and associates,⁶⁵ specimens from 149 patients exhibited dilated cardiomyopathy. Of this subgroup, 18 (12%) had adenoviral DNA demonstrated by PCR in the endomyocardial biopsy specimen. Of these 18 samples, 2 were from neonates, 2 from infants, 2 from toddlers, 4 from older children, 2 from adolescents, and 6 from adults. In a study in adults, 28 explanted hearts from patient undergoing transplant for dilated cardiomyopathy yielded adenovirus type 3 in 25% of cases by nested PCR.⁶⁵¹

Pericarditis

Pericarditis has been associated with severe adenoviral pneumonia. In a patient with adenovirus type 7 pneumonia, electrocardiographic changes consistent with pericarditis were demonstrated, and the virus was isolated in high titer from pericardial fluid at postmortem examination.⁴⁹⁹ In 1995, Mistchenko and coworkers⁴⁷³ reported a 10-month-old boy with fatal pericarditis caused by adenovirus type 7. In serum and pericardial fluid from this child, interleukin-6, tumor necrosis factor- α , and adenovirus-specific immune complexes were identified.

Nervous System

Although CNS disease in adenoviral infection is an uncommon finding, a variety of clinical manifestations have been observed. Both meningitis and encephalitis have been noted as the major manifestations of adenoviral infection or in association with severe disease at other body sites.^{508,512} Huang and coworkers³¹⁸ found that 3.3% of 3298 children less than 18 years of age with positive throat cultures for adenovirus between 2000 to 2008 had symptoms of CNS infection with seizure, altered level of consciousness, headache, and visual hallucinations. Adenovirus types 1, 2, 3, 5, 6, 7, 12, 26, and 32, in isolated instances, have been recovered from both brain and CSF.*

Reyes-Andrade and colleagues⁵⁶⁴ reported a case of adenovirus meningoencephalitis in a previously healthy 15-month-old girl whose presentation mimicked that of bacterial sepsis with petechial rash. They reviewed 18 publications on presumed CNS disease due to adenovirus over the past 4 decades. Among the 92 children involved, there were 57 cases of encephalitis, 12 cases of encephalopathy, 13 cases of meningitis, 9 cases of meningoencephalitis, and 1 case of cerebellitis. Meningoencephalitis often occurs as part of disseminated adenoviral disease in immunocompromised patients, with the most commonly associated serotypes being 2, 3, 5, and 7. Adenovirus serotype 26 DNA was identified in peripheral blood, CSF, urine, and postmortem brain tissue of a 28-year-old woman undergoing radiation therapy for medulloblastoma; progressive neurologic deterioration developed, followed by her eventual death as a result of disseminated adenoviral infection.¹⁶⁵ In two children with respiratory and CNS symptoms, adenoviruses were recovered from spinal fluid.¹⁹⁴ One child was convalescing from herpes zoster and the other from varicella. Adenovirus type 7 was recovered from brain tissue cultures from an elderly patient with chronic schizophrenia.⁴³² In another instance, adenovirus type 32 was recovered from the brain of a man with lymphosarcoma and subacute encephalitis.^{115,579} In an epidemic of adenoviral infection caused by type 7, 25% of the hospitalized patients had symptoms referable to the CNS.^{612,614} Many of the patients died; those who survived had little residual effect.

Too few cases are reported in the literature to predict the prognosis of CNS disease in children accurately. Adenovirus type 2 was isolated from a muscle biopsy specimen from a patient with inclusion body myositis.⁴⁶⁹ Ooi and colleagues⁵¹⁷ reported eight children with adenovirus serotype 21-associated acute flaccid paralysis in the setting of an enterovirus 71-mediated hand, foot, and mouth disease outbreak in Sarawak, Malaysia, in 1997. Of these eight children, four had upper limb monoparesis, two had lower limb monoparesis, and two had paraparesis. Four of the children experienced complete recovery, one was improving at hospital discharge, and three had residual flaccid weakness and wasting. Seven children with initially appearing typical adenoviral infections had transient encephalopathy.⁶³⁷ All these children were infected with adenovirus type 3. On initial evaluation, five had pneumonia, one had follicular tonsillitis, and one suffered from diarrhea. Three of the children were lethargic, two were stuporous, and two were obtunded. All had elevated serum aspartate aminotransferase values (range, 39 to 401 U/L), and CSF evaluations were within normal limits. The neurologic findings resolved in all patients in about 1 week.

Syrbe and colleagues reported a case of adenovirus-associated opsoclonus-myoclonus syndrome due to adenovirus type 3.⁶⁴³ Awosika and colleagues²⁷ reported a fatal case of adenovirus meningoencephalitis that rapidly progressed to myeloradiculitis in an adult patient 6 months after umbilical cord stem cell transplantation for T-cell polymorphic leukemia. Naselli and coworkers⁵⁰¹ reported a case of acute postinfectious cerebella ataxia mimicking myositis due to human herpesvirus-6 and adenovirus in a previously healthy 4-year-old boy who presented with acute onset of lower extremity pain and refusal to walk.

Infection in Immunocompromised Hosts

Adenovirus types 1, 2, 3, 4, 5, 6, 7, 7a, 11, 29, 31, 32, 34, and 35 have been recovered from children and adults who were immunocompromised by

*References 103, 124, 131, 165, 194, 228, 366, 529, 542, 579, 632, 640, 679.

immunodeficiency diseases, malignancies, steroid therapy, immunosuppressive therapy, radiation therapy, and transplantation procedures.* Adenoviral infections occur more frequently in pediatric than in adult hematopoietic stem cell and solid organ transplant recipients.^{32,308,316} Infection is thought to occur as a result of transmission from the donor, reactivation of latent infection, or newly acquired infection.³⁹² McLaughlin and colleagues⁴⁵⁹ examined the incidence of adenovirus infection in 146 children who underwent liver and intestinal transplants. They found that adenoviral infection occurred in 4.1% of liver transplant recipients and 20.8% of intestinal transplant recipients.

In a study of eight children with liver and small bowel transplants and six with just small bowel transplants, Pinchoff and coworkers⁵⁴⁷ noted that all had evidence of adenoviral infection of the graft. In eight of the children, histologic evidence of infection (adenoviral intranuclear inclusions) developed, and these eight had received intensive corticosteroid therapy, had virus isolated from multiple sites, and had persistent positive viral cultures. In a retrospective review of 110 small bowel and liver (combined) transplants in 98 children by Florescu and colleagues, adenovirus infection was found in 38 transplants. Twenty-three of these developed invasive disease, and over 80% occurred within the first year of transplant. In this series, the presence of adenovirus did not have an effect on all-cause mortality.²⁰⁵ For most solid organ transplants, the source of invasive adenoviral disease often is thought to be the transplanted organ.

Kampmann and colleagues³⁵⁵ conducted a prospective study on 155 pediatric stem cell transplant recipients and identified 17% with adenoviremia (26/155). Their study showed that early detection of adenoviremia, withdrawal of immunosuppression, and early antiviral therapy led to resolution of adenoviremia in 81% of the patients. de Mezerville and collaborators¹⁴⁹ retrospectively identified 28 solid organ transplant recipients and 27 hematopoietic stem cell transplant recipients with adenovirus infection at the Hospital for Sick Children in Toronto, Canada. Their study found a similar rate of posttransplant adenoviral infection in solid organ transplant recipients (50.9%) and hematopoietic stem cell transplant recipients (49.1%). de Mezerville's group found a much higher mortality rate in the group of hematopoietic stem cell transplant recipients (30% mortality rate vs. 0% in the solid organ transplant group). Using PCR, Bil-Lula and colleagues reviewed adenovirus infection in 116 patients (98 children, 18 adults) who underwent stem cell transplant. Infection was found in 52 patients (44.8%). Although overall mortality in infected patients was 19%, this did not differ significantly from uninfected patients.^{56,179}

Control of adenovirus infection is thought to be T-cell mediated, and patients receiving T-cell-suppressive regimens are thought to be at greater risk for adenovirus disease.⁷¹⁰ Myers and colleagues⁴⁹² demonstrated an increased risk for the development of adenoviral infection in bone marrow transplant recipients receiving alemtuzumab (Campath 1H), a monoclonal antibody used for T-cell depletion, in comparison to patients receiving antithymocyte globulin (ATG), which was composed of polyclonal antibodies directed toward T cells. Avivi and colleagues²⁶ demonstrated that the most important risk factors for progression of adenovirus disease included severe lymphocytopenia (absolute lymphocyte count of less than 200/mm³) and continued immunosuppression. They also found a correlation between lack of cytomegalovirus (CMV) prophylaxis with ganciclovir and risk of progression of adenovirus disease.

Ahmad and coworkers⁸ reported a case of severe adenovirus pneumonia developing after infused infliximab (Remicade) was used to treat a 35-year-old man with Crohn's disease. Infliximab is a monoclonal antibody directed against tumor necrosis factor- α that is used frequently in the treatment of autoimmune and rheumatologic diseases. Ahmad's group emphasized the fact that tumor necrosis factor- α antagonists can impair cell-mediated immunity, an essential component of recovery from adenoviral infection in immunocompromised hosts and therefore can predispose patients to the development of viral pneumonia.

Other groups have demonstrated that having low lymphocyte counts at the time of development of adenovirus infection was predictive of adenovirus viremia and that clearance of infection and host survival were dependent on recovery of adenovirus-specific CD4⁺ T-cell responses.^{285,685,710} Lankester and colleagues⁴⁰⁰ showed that isolation of adenovirus from multiple sites was associated with the development of adenovirus disease. Lins' group⁴¹⁹ demonstrated an association between isolation of adenovirus in peripheral blood and progression or dissemination (or both) of adenovirus disease. High levels of adenovirus viremia (i.e., detection of PCR product at 100-fold or greater dilution of template DNA) have been correlated with fatal outcomes in children receiving allogeneic stem cell transplants.^{598,684}

Baldwin and colleagues³² studied the outcome and clinical course of 105 adenoviral infections in 100 patients after they received bone marrow transplants. The incidence was higher in unrelated donor transplants than in matched sibling donor transplants. Diarrhea and fever were the most common initial findings. Six deaths were attributed to the adenoviral infections; five of the six patients had pneumonia, and four had associated graft-versus-host disease. Three additional patients had severe disease.

In a study involving 532 recipients of hematopoietic stem cell transplants, a 12% incidence of adenoviral infection was noted.³¹⁶ Forty-one patients had infections classified as "invasive," and mortality was 76% in this group. Recipients of allogeneic transplants were more likely to have adenoviral infections than autologous stem cell recipients were.

The most common manifestation of adenoviral infection in pediatric patients with bone marrow transplants at St. Jude Children's Research Hospital was hemorrhagic cystitis, followed by gastroenteritis, pneumonitis, and liver failure.¹⁹⁰ Adenovirus-induced acute hemorrhagic cystitis is a complication encountered after hematopoietic stem cell transplantation and, more rarely, after renal transplantation.^{199,309} Gorczynska and colleagues²⁵⁷ examined the incidence of virus-induced hemorrhagic cystitis in 102 children and adolescents who underwent allogeneic stem cell transplantation. Hemorrhagic cystitis occurred in 25.5% of these children, with 3.9% of the cases attributed to adenoviruses. Another retrospective review of 266 adults undergoing stem cell transplant showed the incidence of adenoviral hemorrhagic cystitis to be 9.8%. Increased risk of cystitis was linked with underlying disease (cancer other than acute leukemia), and T-cell purging with antithymocyte globulin or alemtuzumab. Patients with acute graft-versus-host disease had a decreased incidence of hemorrhagic cystitis.⁴⁸⁰

Shirali and coworkers⁶⁰⁹ noted that demonstration of the adenoviral genome in endomyocardial biopsy specimens from heart transplant recipients was a predictor of graft loss in children. Graft loss with concomitant adenovirus infection has been described in renal transplant patients.^{385,390} Scattered reports have found an association between adenoviral infection and viruria and hemorrhagic cystitis in patients with renal transplants.^{202,398} Fatal and severe cases of subacute meningoencephalitis caused by an adenovirus have been described in bone marrow transplant recipients.^{141,218} Severe necrotizing pneumonia with pulmonary hemorrhage due to adenovirus in a lung transplant patient has been described.⁴⁵⁴

Lion and coworkers⁴²³ conducted prospective quantitative adenovirus PCR screening in weekly stool and peripheral blood samples of 153 allogeneic stem cell transplants in pediatric patients from 1999 to 2005. They found that increased stool adenovirus copy number (greater than 10⁶ copies per gram of stool) preceded detectable viremia in the peripheral blood by almost a week. This permitted early diagnosis of impending invasive infection with a sensitivity of 100% and specificity of 83%. Srinivasan and colleagues⁶²⁷ also looked at the ability of stool adenovirus load to predict adenoviremia in 117 patients undergoing hematopoietic stem cell transplantation. Their data supported the conclusions of Lion et al., but they found stool adenovirus load of greater than 10⁶ copies per gram of stool demonstrated a sensitivity and specificity of 82%. By using a cut-off of greater than 10⁷ copies per gram of stool, sensitivity decreased to 73% while specificity increased to 86%. Kosulin and colleagues³⁸⁸ sought to evaluate persistence and reactivation of adenoviruses in the gastrointestinal tract. They evaluated biopsies from 143 non-transplant pediatric patients undergoing endoscopy and found persistence

*References 4, 32, 38, 88, 91, 115, 136, 141, 192, 198, 204, 238, 264, 273, 285, 294, 349, 365, 420, 431, 491, 506, 513, 530, 547, 579, 607–610, 616, 625, 663, 689, 717, 742, 749.

of adenovirus in the GI tract in 31% of children (11% of biopsies), with the highest prevalence in the lymphoid cells from the lamina propria of the terminal ileum (61%). Viral proliferation, in contrast, was found to occur in epithelial cells in patients after hematopoietic stem cell transplant. Feghoul and colleagues¹⁹⁶ found that umbilical cord blood transplantation, in vitro T-cell depletion, and graft-versus-host disease grade III and IV were significant risk factors for systemic adenoviral infection. They supported prospective monitoring of adenoviral stool viral load to identify candidates for preemptive treatment to control adenoviral replication and prevent systemic spread of infection. Additional reported risk factors have included grafts from unrelated donors or umbilical cord blood, as well as absence of adenovirus-specific T cells.⁴²¹

In many instances, a fulminant, bacterial, sepsis-like picture with high fever, cough, and lethargy is associated with adenoviral infection in compromised patients.⁷⁴⁹ Severe pneumonia often is demonstrated, both clinically and radiologically, and hepatic involvement with disseminated intravascular coagulation also is a frequent occurrence. Fatalities are reported, and recovery often is slow.

Other Manifestations

Arthritis

Arthritis has been noted in association with adenovirus type 7 infection.⁵²⁷ The illness was characterized by fever, acute respiratory symptoms, erythematous macular rash, aseptic meningitis, and inflammatory arthritis of both knees.

Thyroiditis

In 1964, Swann⁶⁴¹ reported five patients with acute thyroiditis and thyroid enlargement in whom serologic study revealed greater than fourfold rises in titer of adenoviral complement-fixing antibody.

Adrenal Insufficiency

Rai and colleagues⁵⁵⁹ reported a case of transient adrenal insufficiency associated with adenovirus type 40 infection in a previously healthy 6-year-old boy who required mineralocorticoid and glucocorticoid supplementation for 8 weeks, confirming known adrenotropic potential of adenoviruses. Adenoviruses have been demonstrated to induce inflammatory cytokines, enhance adrenal hormone production, and impair adrenal gland steroidogenesis.

Deafness

Deafness of sudden onset was reported in an adult with a 2-day history of sore throat, low-grade fever, rhinorrhea, and cough. Adenovirus type 3 was isolated from the patient's throat, and a greater than fourfold rise in neutralizing antibody titer to this virus was observed.³²⁸

Obesity

Studies have shown that exposure to human adenovirus serotype 36 is associated with increased adiposity in chickens, mice, and nonhuman primates.^{156–158} Continuing work in mouse models shows that adenovirus 36 infection increased macrophage infiltration into adipocytes⁴⁹⁷ and impairs insulin signaling, thus altering glucose metabolism.³⁴⁰ Paradoxically, reduced serum cholesterol and serum triglycerides are seen in the same animal models. Atkinson and colleagues^{24,686} proposed that adenovirus serotype 36 directly affects adipocytes by increasing the number and size of preadipocytes. Vangipuram and associates⁶⁸⁷ explored the possible mechanisms by which adenovirus types 36 and 37 increase adiposity in animal models. They performed ex vivo experiments in human adipocytes and a murine preadipocyte cell line (3T3-L1) and in vivo experiments in the rat model, which demonstrated suppression of leptin mRNA expression, decreased leptin secretion, and increased glucose uptake. In vitro studies show that adenovirus 36 infection causes upregulation of adipogenesis-related genes, along with inflammation that leads to lipid accumulation in cells.⁴⁹⁶ Fatty acid oxidation was also shown to be impaired in in vitro models.⁷⁰⁶ Additional studies have noted possible associations between in vitro infection with adenovirus types 5, 9, and 31 and obesity.^{53–55,695}

Based on studies that adenoviruses increase adiposity in animal models, Atkinson and coworkers²⁴ screened 502 subjects for neutralizing antibodies to adenovirus 36. They detected antibodies to adenovirus

36 in as many as 30% of obese study subjects as opposed to 11% of nonobese subjects. Similarly, they found paradoxically decreased serum cholesterol and triglycerides in patients with antibodies to adenovirus 36. Subsequent studies have shown mixed results. Several studies have shown a correlation between seropositivity to adenovirus 36 and obesity,^{12,23,25,227,664,732} but a longitudinal study from childhood to adulthood among a Finnish cohort failed to demonstrate a causal relationship.⁵⁹¹ In a study of adults, Na et al.⁴⁹⁵ showed that while seropositivity to adenovirus 36 did correlate with overweight body mass index (BMI) (23–25), this relationship did not hold when examining obese individuals (BMI >25). A study completed in Holland and Belgium by Goossens and colleagues²⁵⁶ in active-duty US military personnel⁷⁴ failed to show correlations between adenovirus 36 seropositivity and BMI. Interestingly, Trovato and colleagues showed that adenovirus 36 seropositivity was correlated with greater decrease in BMI and reduction of insulin resistance when subjects were placed on diet and exercise programs.⁶⁶⁵ One study has shown increased serum cholesterol and triglycerides in children with antibodies against adenovirus 36.⁴⁹⁴ Ponterio and colleagues demonstrated the presence of adenovirus type 36 DNA in adipose tissue biopsies of 4 out of 21 overweight and obese adults.⁵⁵⁰ Shang and colleagues⁶⁰⁵ conducted a meta-analysis of 11 case-control studies (2508 cases, 3005 controls) looking at adenovirus 36 infection and obesity. They identified a strong association with adenovirus 36 infection and significantly increased risk of development of obesity, especially in children and those with a BMI of 30 or greater, when compared to nonobese controls. Xu and coworkers⁷³² showed that adenovirus 36 infection was associated with the status of obesity but did not find an association with weight gain through analysis of BMI or BMI z-scores. Additional studies by Whigham and colleagues⁷¹² demonstrated that human adenovirus serotype 37 also is associated with an increase in adipocyte differentiation and reduced serum triglycerides but increased serum cholesterol.

Congenital and Neonatal Infections

Neonatal and congenital adenoviral infections reflect disseminated infection with the involvement of multiple organs.^{3,77,113,190,377,519,632} Major manifestations include hepatosplenomegaly, progressive pneumonia, hepatitis, and thrombocytopenia. Towbin and colleagues⁶⁶⁰ reported intrauterine adenoviral myocarditis manifested as nonimmune hydrops fetalis. Illnesses frequently appear initially as an early-onset sepsis syndrome. An infant was reported with a congenital pleural effusion from which type 3 adenovirus was recovered.⁴⁶⁶

A recent study by Couroucli and associates¹²⁹ has noted an association between adenoviral infection and bronchopulmonary dysplasia (BPD). They found a significant increase in the frequency of adenovirus genome in tracheal aspirates from patients with BPD versus controls.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of adenoviral infection must be subcategorized on the basis of the major clinical manifestations. In many instances, specific clinical symptoms such as pharyngoconjunctival fever or epidemic keratoconjunctivitis can lead to strong suspicion of the adenoviral etiology. With other, more general respiratory diseases such as pharyngitis, bronchitis, croup, bronchiolitis, and pneumonia, the adenoviral etiology cannot be established on clinical grounds. Fever in adenoviral respiratory infections tends to be higher than that occurring in parainfluenza and RSV infections but similar to that in influenza A and B viral infections.⁵⁵⁶ High and prolonged fever occurs as commonly in adenoviral infections as it does in bacterial respiratory infections. Because the symptom triad of fever, pharyngitis, and conjunctivitis is virtually unique to pharyngoconjunctival fever, establishing the diagnosis of this disease should be easy. Generalized diseases that occasionally might be confused with pharyngoconjunctival fever include leptospirosis, psittacosis, *Mycoplasma pneumoniae* infection, Q fever, Newcastle disease virus infection, and prodromal measles.

In pharyngitis, adenoviral infection must be differentiated both from other viral diseases, such as those caused by Epstein-Barr virus, parainfluenza and influenza viruses, and enteroviruses, and from streptococcal

disease. In a young child, follicular pharyngitis is more likely to be caused by adenoviral than by streptococcal infection.

Adenoviral pneumonia in young children frequently is not distinguishable on clinical grounds from that caused by bacteria. In older children and adolescents, in particular, adenoviral pneumonia often can be differentiated from bacterial disease by its bilateral nature. Differentiating adenoviral illness from disease caused by *M. pneumoniae* is more difficult; however, cold agglutinin titers generally are higher and more persistently positive in mycoplasmal disease.

Adenoviral eye disease must be differentiated from that caused by viruses of the herpes group, enteroviral epidemic conjunctivitis (acute hemorrhagic conjunctivitis),^{418,739,740} and *Chlamydia* spp. and bacteria, including *Neisseria gonorrhoeae*.

Diarrhea caused by enteric adenoviruses can be differentiated from other viral diarrheas by electron microscopy, by identification with ELISA, and by specific culture of the enteric agents in Graham 293 cell culture. Enteric bacterial and parasitic agents also must be considered in the differential diagnosis.

The high, relatively prolonged fever occurring in association with lymphadenopathy, exanthem, and enanthem noted with adenoviral infection often causes confusion with Kawasaki disease.⁵⁷⁴ Because Kawasaki disease must be treated early with intravenous immunoglobulin, adenoviral infections should be considered early and appropriate studies performed. Jordan-Villegas and colleagues³⁴⁶ conducted a study of almost 400 children diagnosed with Kawasaki disease in a 10-year period. They found that patients with concomitant respiratory viral infections diagnosed by DFA and/or viral culture had a higher frequency of coronary artery aneurysms. Jaggi and colleagues³²⁹ highlighted challenges in interpreting detection of adenovirus by respiratory viral PCR among patients meeting criteria for complete or incomplete Kawasaki disease. They cautioned that detection may represent viral shedding and persistence, however, noting that adenovirus was detected in 8.8% to 25% of patients meeting criteria for complete and incomplete Kawasaki disease, respectively. Song and collaborators⁶²² noted that the most common clinical feature between adenovirus and Kawasaki disease was conjunctivitis. They found that features most consistent with conjunctivitis due to adenovirus included unilateral onset, prominent tearing (as compared to purulence), and follicular hyperplasia; CRP was consistently higher among their subjects with Kawasaki disease; and lower viral burden was more likely to be associated with complete Kawasaki disease.

Specific Diagnosis

Adenoviral infection can be diagnosed specifically by isolation of virus in an appropriate tissue culture system, direct antigen detection assay, or by DNA PCR. Most adenoviral types can be recovered from clinical specimens in primary or diploid cultures of human embryonic kidney.⁴⁰⁹ The enteric viral types 40 and 41 can be grown in Graham 293 cells.^{646,699} The rapidity of detection of adenoviruses by culture is enhanced by centrifugation of specimens in shell vials or plastic-welled plates.^{171,183,438}

Direct identification of adenoviruses in respiratory secretions by radioimmunoassay, immunofluorescence techniques, and ELISA now is performed widely.^{79,438,465,560,574,589,593,654} However, in general, the sensitivity, when compared with that of virus isolation, is relatively low; on the other hand, the specificity is high (>95%). Rocholl and colleagues⁵⁷⁴ demonstrated the impact of rapid diagnosis of adenoviral respiratory disease with an adenoviral direct fluorescent antibody technique by noting discontinuation of empiric antibiotic use in a retrospective analysis of hospitalized patients with respiratory cultures positive for adenovirus. Rapid techniques for the identification of enteric adenoviruses in general have been sensitive and specific.^{7,259,277,291,594,671,724} However, in newborns, false-positive results with a latex agglutination test have been reported.³²⁴ Several techniques using DNA probes have been studied for the rapid identification of both respiratory and enteric adenoviral infection.^{82,323,645} PCR assay also is useful for the rapid detection of adenoviral infection and is rapidly becoming the gold standard of diagnosis alongside tissue culture isolation.* PCR assay

is particularly useful for identifying adenoviral DNA in formalin-fixed, paraffin-embedded tissues and other biopsy and postmortem specimens.^{65,267,433,445,609,666}

Several groups have demonstrated the utility of PCR detection of adenoviral DNA in acute respiratory infections in immunocompetent patients.^{2,191,574,608,733} The first multiple PCR assay for detection of respiratory viruses (Luminex xTAG Respiratory Viral Panel) was approved in January 2008, and more than nine commercially available assays have been approved since then.⁷⁵¹ Kuypers and colleagues³⁹⁴ demonstrated significantly increased sensitivity of quantitative real-time PCR assay over fluorescent antibody detection of adenoviruses. They showed that 77.7% of respiratory specimens that were negative for adenovirus by fluorescent antibody detection were positive by PCR detection of adenovirus DNA. This increased sensitivity was replicated by Stroparo and colleagues.⁶³⁸ Multiple PCR assays have been developed to detect multiple serotypes of adenovirus.^{419,733} Buckwalter and colleagues developed real-time PCR for qualitative detection of 57 serotypes of adenovirus with high sensitivity and specificity in a variety of clinical samples.⁸¹ Others have demonstrated similar multiplex assays for adenovirus although narrower in scope.⁵²⁰ Aberle and colleagues² were able to detect adenoviral DNA with a nested PCR assay in acute-phase sera collected within the first week after the onset of symptoms in 72% of immunocompetent children experiencing their first adenoviral infection and in 25% of those experiencing recurrent infection.

It is important to note that the commercially available multiplex PCR assays to detect respiratory viral pathogens, particularly the BioFire Film Array Respiratory Panel (BioFire Diagnostics; Salt Lake City, Utah), had lower sensitivity for adenovirus group C, serotypes 2 and 6.²⁹ The package insert recommended testing of negative specimens using alternate methods to detect adenovirus when infection is clinically suspected. In April 2013, version 1.7 was released. Doern and colleagues¹⁶¹ specifically looked at the Film Array assay's ability to detect adenoviruses. They found that version 1.7, which includes a second adenovirus assay, demonstrated improved sensitivity in both retrospective and prospective studies with improvements in sensitivity from 66.6% to 90.5% and from 42.7% to 83.3%, respectively. However, Song and colleagues⁶²⁴ analyzed 4750 nasopharyngeal specimens for respiratory viruses in a large pediatric cohort and found that 146 (3.1%) of specimens were positive for adenovirus using version 1.7. They noted an additional 220 specimens that were negative by version 1.7 to be positive for adenovirus by a laboratory-developed adenovirus-specific PCR, representing a 4.6% increase in adenovirus detection. They found that the adenovirus-specific PCR had lower limits of detection, had difficulty with detection of nonrespiratory species, and confirmed the manufacturer's data that species A and F (serotypes 18, 31, 40, and 41) were detected with very low sensitivity. The group cautions use of this assay when evaluating immunocompromised patients for adenoviral infection for diagnostic, therapeutic, and epidemiologic concerns.

Interpretation of a positive result from nasopharyngeal specimens is challenging, however, as prior studies have shown that adenovirus can be detected in up to 11% of healthy, asymptomatic children by PCR versus 0.6% by culture. Additionally, interpretation of the clinical significance of a positive PCR specimen for species F adenoviruses (subtypes 40 and 41) from a respiratory specimen remains unclear. Song and collaborators⁶²³ suggest the use of both viral load quantitation as well as species/serotype identification when using PCR-based testing to aid in assessment of the clinical significance of a positive PCR result. Other groups have demonstrated the utility of using serum PCR assays to diagnose and monitor adenoviral infection and disease in immunocompromised hosts.^{400,598} Lion's group⁴²² developed a species-specific real-time quantitative PCR assay that allows detection and quantification of 51 human adenovirus subtypes. They showed that detection of adenovirus DNA in the peripheral blood of allogeneic bone marrow transplant recipients preceded the onset of clinical symptoms of disseminated adenoviral disease by a median of 3 weeks. Two other groups^{410,702} have used real-time quantitative PCR assays to detect adenoviral DNA load to aid in both the diagnosis and management of disseminated adenoviral infections in immunocompromised patients. Ebner and colleagues¹⁷³ presented a two-stage PCR algorithm for diagnosis in immunosuppressed patients. Although algorithms for detection and

*References 2, 15, 65, 173, 174, 191, 198, 286, 338, 339, 394, 400, 410, 422, 459, 481, 482, 530, 574, 598, 608, 702, 733.

typing of adenoviruses have been used in the past,^{173,456} the use of type-specific PCR and other techniques such as reverse-line-blot has made serotyping more efficient.^{81,89}

Multiplex PCR to detect multiple different viruses in a clinical sample (respiratory secretions, stool, blood, etc.) are now becoming widely available. Commercial as well as “home-made” assays can now test for up to 13 different viruses with fast turnaround (1–4 hours) and excellent sensitivity and specificity.^{195,226,268,275,301,405,444,682} The availability of cheap, reliable, and fast PCR kits has raised the question of whether the detection of viral genetic material can be attributed to true infection or shedding of dead virus from a past event. Kalu and colleagues³⁵⁴ showed in a cohort of 76 children with 581 episodes of upper respiratory infection that adenoviruses of the same type and strain would persistently be detected by PCR in nasopharyngeal washes of the same host for over 200 days. The authors caution that clinical interpretation of PCR test results is necessary, as most practitioners do not have access to phylogenetic analysis. Respiratory viral coinfection has also made interpretation of positive results challenging, with studies showing 55% to 63% of patients having adenovirus coinfection.^{623,624} Manji and colleagues⁴⁴² conducted a prospective multicenter study of the Adenovirus R-gene assay (Argene/bioMérieux; Verniole, France) at three major US medical centers from September 2010 through November 2011. They tested 395 nasopharyngeal aspirates and 1186 nasopharyngeal swabs obtained from patients who had symptoms of a respiratory illness. This real-time PCR assay detects but does not differentiate among adenovirus serotypes. They found overall sensitivity for nasopharyngeal aspirates and nasopharyngeal swabs to be 100% and 98.9%, specificity 100% and 98.9%, positive predictive value 97.6% and 100%, and negative predictive value 100% and 99.9%, respectively.

Many hospitals relied on fluorescent antibody staining, shell vial culture, and viral culture to identify adenovirus infection. Multiplex PCR, especially for the diagnosis of respiratory viral illness, as well as single-plex adenovirus PCR is quickly taking the place of these methods.

Acute infection also can be diagnosed serologically by the expression of specific serum IgM antibody.⁴⁶⁵ Infection can be confirmed serologically by the demonstration of a rise in antibody titer in two sequential serum samples. Antibody response to the adenovirus group antigen can be detected by complement fixation or ELISA. Type-specific antibodies can be determined by neutralization, ELISA, or hemagglutination inhibition.

Currently, there are 13 available commercial GI multiplex PCR assays, but only two are FDA-approved syndromic multiplex assays for detection of bacterial, viral, and parasitic pathogens causing gastroenteritis (Luminex xTAG GPP, BioFire Film Array GI Panel).⁷⁵¹ Ye and coworkers⁷³⁶ conducted a prospective pilot study of five healthy asymptomatic infants in whom weekly stool samples were collected over the first 2 years of life. Stool samples were tested for six enteric viruses including adenovirus. Approximately 40% of samples were positive for virus detection by PCR with adenovirus detected most frequently in 25.6% of samples. They noted frequent asymptomatic shedding of adenoviruses as detected by PCR for up to 3 months in infants without gastrointestinal symptoms. Buss and coworkers⁸⁴ showed a sensitivity of greater than or equal to 94.5% and specificity greater than or equal to 97.1% for all 22 panel targets.

TREATMENT

During the febrile period of illness, adequate hydration should be maintained and excessive activity discouraged. The fever may be controlled with acetaminophen. In children with eye involvement, careful attention should be paid to the possibility of secondary bacterial infection. If local purulence develops, specimens should be procured for culture and topical antimicrobial therapy started. The use of steroid-containing ophthalmic ointments should be avoided.

A consistent, safe, and effective therapy to treat adenovirus infection has yet to be established. Whereas vidarabine, ribavirin, and cidofovir demonstrate good activity against adenoviruses *in vitro*, several studies have shown only limited success with the use of vidarabine, ribavirin, ganciclovir, and cidofovir in treating adenovirus disease in humans.^{426,487} The potential beneficial effects must be weighed carefully against the adverse side effects of these antiviral agents, including myelosuppression,

pancytopenia, and nephrotoxicity. Walls and coworkers⁷⁰³ conducted a retrospective study of 26 patients undergoing hematopoietic stem cell transplantation. They were unable to demonstrate a direct correlation among adenoviral DNA load, clinical features, and severity of disease. They also identified two children who experienced low-level adenoviral viremia after undergoing hematopoietic stem cell transplantation; the children cleared the virus without treatment. Williams and colleagues⁷²⁰ created an algorithm to risk-stratify pediatric oncology and stem-cell transplant patients with adenovirus infection to determine who would benefit from cidofovir therapy without unnecessary risk of nephrotoxicity. They determined high-risk patients to be those with recent transplant (<60 days allogeneic or <180 days autologous), those with graft-versus-host disease, and those on immunosuppressive therapy. These patients would benefit from cidofovir, while those without these risk factors would do well without treatment. Their algorithm was validated in a small prospective cohort of 11 patients.⁷²⁰ Matthes-Martin and colleagues developed an algorithm for preemptive antiviral therapy for adenovirus infection based on weekly monitoring of adenovirus viral load in blood and stool. Based on their review of existing literature, they suggest treatment when greater than or equal to 10^2 copies/mL adenovirus is detected in peripheral blood or greater than or equal to 10^6 copies/g feces are detected. They also advised reduction in immune suppression if possible until the serum adenoviral load is less than 10^2 copies/mL.⁴⁵²

Ribavirin is a guanosine nucleoside analogue used for the treatment of severe RSV infection in its inhaled form and for the treatment of chronic hepatitis C infection. In a number of instances, immunocompromised patients with disseminated adenoviral infection have been treated with ribavirin administered intravenously, and successful outcomes have been reported.^{19,356,417,455,489,569,729} In one instance, a loading dose of 30 mg/kg per day divided into three doses was followed by maintenance therapy with 15 mg/kg per day.⁴⁵⁵ Gavin and Katz²³⁸ reported complete clinical recovery in two of five patients with severe adenovirus disease. A later study by Lankester and associates³⁹⁹ demonstrated no effect on plasma adenoviral DNA load despite initiation of treatment with ribavirin at the first onset of clinical symptoms in four pediatric patients receiving allogeneic stem cell transplants. Intravenous ribavirin is available in the United States only as an emergency investigational drug as it is not approved by the FDA. Data on its use, efficacy, and safety are still very limited.⁵⁶⁹

The antiviral agent with the most promise to date has been cidofovir (Vistide), a cytosine nucleoside analogue with efficacy against several DNA viruses, including CMV, HSV, polyomaviruses, and adenoviruses. Cidofovir was used successfully in treating a 17-year-old boy who had received a stem cell transplant and had severe adenoviral gastroenteritis.⁵⁶⁶ Ljungman and colleagues⁴²⁷ conducted a study of cidofovir for the Infectious Diseases Working Party for Blood and Marrow Transplantation (EMBT). They demonstrated successful treatment of adenovirus infections in 69% of allogeneic hematopoietic stem cell transplant recipients, primarily with a 5-mg/kg dose of cidofovir given intravenously one time per week for the first 3 weeks and every other week after that, along with concomitant use of probenecid and intravenous fluid hydration. Other studies have shown a similar effect with reduced dosing of cidofovir at 1 mg/kg per dose given three times a week.^{283,426,487} A case report by Fanourgiakis and colleagues¹⁹² demonstrated successful treatment of severe (grade IV) hemorrhagic cystitis in a 34-year-old man by intravesical instillation of 5 mg/kg of cidofovir in 100 mL saline twice daily. This method avoided the known nephrotoxicity associated with cidofovir. Saquib and colleagues reported on two adult renal transplant patients with adenovirus viremia successfully treated with cidofovir along with intravenous immune globulin and concurrent reduction in immune suppressive therapy.⁵⁹⁵ Yusuf and coworkers⁷⁴⁸ reported complete resolution of clinical symptoms in 57 of 58 pediatric hematopoietic stem cell transplant recipients treated with cidofovir. Wallot and colleagues⁷⁰¹ had some success using reduced-dose cidofovir, inhaled nitric oxide, and decreased immunosuppression to treat two liver transplant recipients with disseminated adenoviral disease and acute respiratory distress syndrome. Lugthart and coworkers⁴³⁴ evaluated cidofovir efficacy in 36 pediatric allogeneic hematopoietic stem cell transplant recipients who developed adenoviremia. While they noted rapid decline in adenoviral load and clearance from peripheral blood

with cidofovir treatment, they noted that this coincided with T-cell and natural killer–cell reconstitution. They cautioned that cidofovir efficacy may be overestimated if the contribution of T cells, and possibly natural killer cells, reconstitution is not considered as well. Hydration and coadministration of probenecid may help minimize cidofovir-induced nephrotoxicity.

Caruso Brown and coworkers⁹² reported the safety of a single dose of cidofovir in an open-label, nonrandomized pilot study of 12 pediatric hematopoietic stem cell transplant recipients with symptomatic adenovirus infection, nucleoside-resistant CMV or HSV, and/or human papovavirus infections. Four of seven patients with adenovirus infection were successfully treated and eventually cleared their infections. Two patients in their cohort developed evidence of acute kidney injury after a single dose of cidofovir (one recovered, one progressed to chronic kidney disease), and two patients developed late nephrotoxicity. Ganapathi and colleagues²⁹ conducted a retrospective chart review of 16 patients who received 19 courses of cidofovir for asymptomatic viremia as well as probable and definite adenovirus disease in hematopoietic stem cell transplant recipients and multiple solid organ transplant recipients (including lung, heart, combined kidney and liver, and multiple visceral transplants). Patients experienced an average 50% increase in creatinine from baseline. However, this was found to be a transient effect as creatinine normalized upon discontinuation of cidofovir.

Mynarek and colleagues⁴⁹³ reported data prospective monitoring of serum adenovirus PCR in 238 consecutive pediatric allogeneic hematopoietic stem cell transplant recipients over a 9-year period. They found that peak blood adenovirus levels greater than 10^4 copies/mL was an independent risk factor for poor survival. Additionally, peak serum adenovirus levels greater than or equal to 10^4 copies/mL was associated with peak stool viral loads greater than 10^6 copies/mL. Using univariate and multivariate logistic regression analysis, they found that detection of adenovirus in peripheral blood before day +50 and age less than 6 years at transplant was associated with adenoviremia greater than 10^4 copies/mL. They recommend preemptive antiviral therapy in patients with serum adenovirus PCR greater than 10^4 copies/mL, those with at least two samples greater than 10^3 copies/mL, and those with increasing viral loads. They also recommended treating end-organ infection as early as possible irrespective of blood viral load.

Brincidofovir (3-hexadecyloxy-1-propyl-cidofovir) is a new oral antiviral drug made by Chimerex and is a lipid conjugate of cidofovir. The lipid moiety allows entry into the cell, and intracellular phospholipase cleavage prevents easy exit from the cell. Brincidofovir is less nephrotoxic than cidofovir as it does not accumulate in renal tubules due to the fact that it is not a substrate for renal organic anion transporter 1. It has broad activity against five double-stranded DNA viruses in vitro including BK polyomavirus, vaccinia, and molluscum contagiosum.¹¹¹ Brincidofovir is currently undergoing phase III clinical trials to treat adenovirus infections in allogeneic hematopoietic stem cell transplant recipients (Phase III, Open-labeled, Multicenter Study of Safety and Efficacy of Brincidofovir [CMX001] in the Treatment of Early Versus Late Adenovirus Infection [the AdVise Study]). Subjects receive 100 mg BCV biweekly (or 2 mg/kg biweekly for subjects under 50 kg) for 12 weeks and are assessed for adenovirus clearance from blood, respiratory secretions, urine, and stool.⁷²³ Evaluation of treatment of poxviruses in mouse models is also ongoing.¹⁶⁴

Paolino and colleagues were the first to report successful recovery from disseminated adenovirus infection in a pediatric stem cell transplant patient using brincidofovir after treatment failure with cidofovir.⁵²⁸ McKillop and coworkers⁴⁵⁸ reported successful treatment of disseminated adenovirus disease complicated by progressive necrotizing hepatitis with one dose of cidofovir and an 8-month course of brincidofovir 4 mg/kg per dose two times a week.

Florescu and colleagues retrospectively reviewed salvage treatment of adenovirus infection with brincidofovir (after failure with cidofovir) in 13 solid organ and stem cell transplant patients; 9 patients had a significant lowering of viral load, whereas 4 patients did not. The former group did have a statistically longer survival time, and no patients were discontinued due to drug side effects.²⁰⁶

Further studies into possible immunotherapies for the treatment of adenovirus infections also have been investigated. Feuchtinger and

associates²⁰¹ were able to perform successful and safe adoptive transfer of adenovirus-specific, T-cell immunity in five of six patients with documented adenovirus infection after allogeneic hematopoietic stem cell transplantation. This effect was found to be independent of the T-cell dose. Furthermore, the adenovirus-specific T-cell expansion was sustainable, and proliferation of the adenovirus-specific T cells was unimpaired by adenovirus viremia, in contrast to the myelosuppressive effects seen with CMV viremia. Currently, emphasis of study is on the efficient and effective in vitro manufacturing of cytotoxic T-lymphocytes for use in immunocompromised individuals.^{9,221,240,611,750} Di Nardo and coworkers¹⁵⁹ reported successful treatment of a 10-year-old boy with congenital amegakaryocytic thrombocytopenia who underwent T-cell-depleted haploidentical hematopoietic stem cell transplantation. He developed severe adenovirus respiratory disease requiring extracorporeal membrane oxygenation. Despite treatment with cidofovir, he developed hemorrhagic cystitis. Adoptive T-cell transfer of adenovirus-specific T cells was performed, allowing the patient to come off extracorporeal membrane oxygenation in 7 days and off the mechanical ventilator in 10 days. They noted that absolute lymphocyte count increased following infusion and C-reactive protein declined, while central memory and effector memory CD4⁺ T cells increased and NK cells decreased. Feucht and colleagues²⁰⁰ conducted a clinical trial of donor-derived adoptive T-cell transfer in 30 hematopoietic stem cell transplant patients with adenovirus viremia or disease refractory to antiviral therapy after 2 weeks. They utilized hexon-specific T cells, primarily of the T-helper (Th1) phenotype and late effector T-cell stage, isolated via the interferon gamma (IFN- γ) capture technique. Infusions were well tolerated with no significant side effects or development of or worsening of alloreactivity (e.g., graft-versus-host disease). Sustained and protective T-cell responses were detected up to 6 months after adoptive T-cell transfer. Patel and colleagues⁵³⁶ reported the case of a 26-month-old male recipient of a liver transplant for hepatoblastoma who developed adenoviremia as well as adenovirus-associated gastroenteritis and hepatitis. The child was able to recover with reduced immune suppression alone without antiviral therapy, thereby highlighting the importance of reduced immunosuppression.

Teuchner and colleagues⁶⁵³ studied *N*-chlorotaurine (NCT), a compound produced by monocytes and granulocytes during the oxidative burst, in a double-blind investigation of adult patients with epidemic keratoconjunctivitis. Among the group of 60 patients, 33 were treated with a 1% aqueous solution of NCT, and 27 were treated with gentamicin. They analyzed both subjective and objective scores. In the total study group, the NCT-treated subjects were subjectively better than the gentamicin-treated patients at day 8, but there were no objective differences. However, in severe infections, both the subjective and objective scores were better on days 4 and 8 in the NCT-treated patients. They concluded that NCT treatment was well tolerated and that it shortened the duration of illness. A study of the use of 1% cidofovir eye drops with and without 1% cyclosporine eye drops to treat adenovirus-associated keratoconjunctivitis was conducted by Hillenkamp and colleagues.³⁰⁶ This study demonstrated significant local toxicity in the skin of the eyelids and conjunctiva but a decreased frequency of severe corneal opacities associated with the use of cidofovir. A novel drug, NVC-422, has shown good in vitro activity against adenovirus types 5, 8, 19, and 37.³³⁶ This compound is an analogue of NCT that has been modified to gain better stability in solid-state solution. A phase II clinical trial for adenoviral conjunctivitis is ongoing.⁷⁴⁵

Human fibroblast–derived interferon, applied topically, was used to treat epidemic adenoviral keratoconjunctivitis in a comparative trial.⁵⁷⁷ The duration of illness was reduced in the patients treated with interferon, but many of the control patients received dexamethasone. A child with combined immunodeficiency and severe, diffuse adenovirus type 7a pneumonia improved dramatically after receiving a large dose of high-titer adenovirus type 7a immune serum globulin.¹³⁶

PREVENTION

Serious incapacitating epidemics caused by adenoviruses in military recruits in basic training led to the development of adenoviral vaccines.^{18,406} The initial vaccines were formalin-inactivated preparations

of monkey kidney tissue culture-grown virus and were administered parenterally.^{17,266,303} These vaccines achieved only limited success because of variable degrees of potency in different vaccine lots.⁴⁰ An inactivated adenoviral vaccine that contained types 3, 4, and 7 was prepared in monkey tissue culture for trial in children.⁶⁸¹ Three doses of this vaccine resulted in high levels of neutralizing antibody to the three viral types, and this antibody persisted in most infants for at least 1 year. Many of the initial lots of inactivated adenoviral vaccine were found to contain live simian adenoviruses that were capable of producing neoplasms in suckling hamsters. Because of this finding, inactivated vaccine trials were discontinued. Next, a live, attenuated adenovirus type 4 vaccine that was cultivated in human diploid tissue culture was developed and administered orally by enteric-coated capsule to volunteers. Asymptomatic gastrointestinal infection occurred, and a good serum-neutralizing antibody response was elicited.^{266,620,628} Most recipients of live oral vaccine excrete virus in stool for several days to a month after being vaccinated. With military use of the vaccine, shedding in stool was not associated with transmission of the virus to nonimmune contacts.⁴⁸³ In other studies of married couples and families with children, virus was transmitted to nonimmune contacts.^{483,629} Transmission usually occurred without illness.⁴⁸³

The administration of live, enteric-coated, type 4 and 7 adenovirus vaccine resulted in a significant decrease in the incidence of ARD in military recruits.^{168,255,644} Unfortunately, adenoviral vaccines no longer are available, and the incidence of ARD in military recruits again is a significant problem.^{33,261,384,590} This vaccination program was terminated in 1999. However, after a subsequent rise in the incidence of acute respiratory disease and deaths in military servicemen,⁵⁵³ vaccination was resumed. A new live oral vaccine for type 4 and 7 human adenoviruses is now licensed and in use since 2011.⁶⁶⁷ Few attempts have been made to protect children with live adenoviral vaccines. In one study, live enteric-coated adenovirus type 4 vaccine was given to children aged 5 to 11 years. Asymptomatic gastrointestinal infection resulted from administration of the vaccine. Because the major cause of pharyngoconjunctival fever caused by adenoviruses is swimming in contaminated water, discretion in bathing locations is advised. Swimming pool water should be chlorinated adequately, and pool filtration systems should be inspected daily. Ill individuals should be excluded from swimming pools during their illness and for at least 2 weeks after recovery.

PROGNOSIS

The overall prognosis of adenoviral infection generally is excellent. Secondary bacterial complications, if untreated, can result in prolongation of illness and permanent sequelae in some instances. The prognosis of adenoviral infection in the very young and in immunocompromised patients must be guarded.

SUBSECTION IV DNA—*Hepatoviridae*

Hepatitis B and D Viruses

157

Yen H. Pham • Daniel H. Leung

HEPATITIS B VIRUS

Hepatitis B virus (HBV) infection remains a significant health problem worldwide. Review of worldwide seroprevalence data shows a decrease in prevalence of chronic HBV infection, from 4.2% to 3.7%, but an increase in absolute numbers of persons chronically infected, from 223 million to 240 million between 1990 and 2005 despite the availability of the HBV vaccination. In the United States, the total number of persons

with chronic hepatitis B is estimated at 2 million, although acute cases have dropped to only 0.9 cases per 100,000 persons in 2014.^{158,222,307} Individuals chronically infected with HBV are at risk for developing cirrhosis and hepatocellular carcinoma (HCC). Worldwide mortality is still estimated at 0.5 to 1.2 million deaths per year.¹⁷⁰ Most individuals with chronic HBV infection acquired the virus through vertical transmission, which can now be prevented in the majority of cases by active and passive immunization.

Biology

HBV is the prototype of a family of deoxyribonucleic acid (DNA) viruses called *hepadnaviruses* (hepatotropic DNA viruses). This group consists of enveloped, coated, double-stranded DNA viruses with similar structure and genome organization. All primarily infect the livers of their respective hosts and can cause acute and chronic infections.

The three types of particles found in the sera of HBV-infected people—the Dane particle and two subviral particles, one spherical and the other filament shaped—have influenced how we serologically monitor for HBV. All three types share a common surface antigen, hepatitis B surface antigen (HBsAg), but only one, the Dane particle, contains viral DNA and is capable of replication. The Dane particle, or whole virion, is 42 nm in diameter and contains a core, or nucleocapsid, enclosing the DNA. The outer shell is composed of large amounts of hepatitis B surface proteins in a lipoprotein envelope, which is derived from host cells. Inside this shell is the nucleocapsid, an icosahedral structure composed of 240 core protein subunits with regular penetrating channels. These nucleocapsid proteins are detected serologically as hepatitis B core antigen (HBcAg). Within this nucleocapsid are also contained the viral genome and polymerase. Hepatitis B envelope antigen (HBeAg), a marker of viral replication, is a soluble antigen produced from the same open reading frame as is HBcAg. However, unlike core antigen, e antigen is secreted into serum, where it is thought to have a role in induction of tolerance to HBV. The viral genome is composed of double-stranded circular DNA that can be relaxed or closed depending on the stage in the reproduction cycle.

The subviral particles (spheres and filaments) are composed of envelope proteins and host-derived lipid components.²⁵⁴ Neither the filament nor the sphere contains nucleic acid. These particles are abundant in the serum of infected individuals (10^6 – 10^{14} particles/mL), and they are highly immunogenic, stimulating the production of neutralizing antibodies. One hypothesis is that they absorb neutralizing antibodies, thus shielding the intact virion from the host immune response. Subviral particles were used to produce the first effective HBV vaccine.²⁸⁰

Molecular Virology

The compact partially double-stranded viral genome contains four open reading frames (ORFs): (1) precore/core (preC/C), which encodes the e antigen (HBeAg) and core protein (HBcAg); (2) P for polymerase (reverse transcriptase); (3) PreS1/PreS2/S for surface proteins (three forms of HBsAg, small [S], middle [M], and large [L]); and X for a transcriptional transactivator protein (Fig. 157.1).

Nine HBV genotypes and multiple subgenotypes have been identified by use of polymerase chain reaction (PCR)-restriction fragment length polymorphism analysis of the complete viral genome.^{140,180} They have been designated A through I and differ in genome length, the size of ORFs and proteins translated, and the development of various mutations.¹⁶⁰ Genotype and subgenotype predominance varies by geographic location. Genotype A is found in northwestern Europe, North America, and Africa. Genotypes B and C are characteristic of southeast Asia. Genotype D has a worldwide distribution but predominates in the Mediterranean area. Genotype E is found in Africa, and genotypes F and H are found in South and Central America.^{180,278,309} In a US study, a strong statistical association has been found between genotype and ethnicity and genotype and place of birth: genotypes A and D were detected more often in whites, whereas Asian carriers were infected with genotypes B and C; 77% of carriers born in the United States were infected with genotype A, but the genotype of carriers born outside the United States reflected their place of origin.^{279,309}

The clinical differences among HBV genotypes are being elucidated. Infection with genotype C was found in Taiwanese adults to be associated with more severe liver disease and HCC in those older than 50 years of age, whereas genotype B is associated with HCC in younger persons.¹³⁹ In a study of 487 Chinese HBV-infected children, genotype C was more common (76.4%) than genotype B (22.3%) or genotype D (1.3%). Children with chronic HBV B2 had less severe inflammation and fibrosis than those with HBV C2.³²⁹ An association of genotype with response

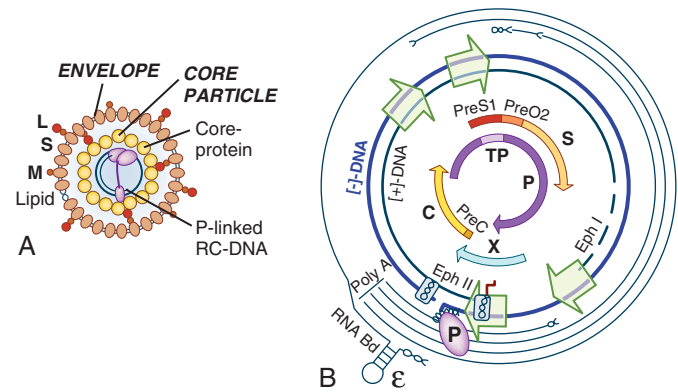

FIG. 157.1 Molecular features of hepatitis B virus. (A) Virion structure. Infectious virions consist of an outer envelope with the lipid-embedded surface proteins small (S), medium (M), and large (L), and an icosahedral inner nucleocapsid harboring the viral genome as a relaxed circular (RC)-DNA. (B) Genome organization. Outer lines denote viral transcripts, arrowheads denote transcription starts, and ϵ symbolizes the RNA encapsidation signal on pregenomic (pg)RNA. The two DNA strands are shown as present in RC-DNA to highlight the relative positions of RC-DNA—typical features; however, the viral RNAs encoding the open reading frames (ORFs) depicted in the center are transcribed from covalently closed circular DNA. (From Nassal M. HBV cccDNA: viral persistence reservoir and key obstacle for a cure of chronic hepatitis B. *Gut*. 2015;64[12]:1972–1984.)

to interferon- α (IFN- α) treatment also has been demonstrated. A study from Taiwan analyzed the responses of 58 patients with chronic HBV infection genotypes B and C to treatment with IFN- α . The patients with genotype C had higher aminotransferase levels at baseline. After 48 weeks of follow-up, only 15% of those with genotype C were HBeAg negative and HBV DNA negative as compared with 42% of those with genotype B.¹⁴² The genotype of HBV can influence the outcome of HBV infection in children because it can affect the frequency of HBeAg positivity, the age at which HBeAg loss occurs, and the mode of transmission.^{141,161,201}

Mutations affecting all ORFs of the HBV genome have been described. Most viral genomes carry more than one mutation, and most individuals are infected with more than one variant. Some of the mutations are thought to contribute to viral latency, level of infection, severity of liver disease, and vaccine escape. Mutations in the core gene, the precore region, and the promoter for C have become clinically important. The group best studied is the precore mutants, which result in lack of HBeAg production, even in the presence of active viral replication, the so-called HBe antigen–negative infection. In contrast to the situation in persons with wild-type virus, in whom absence of HBeAg usually signifies absent HBV replication and mild liver disease (see later discussion), in HBeAg-negative hepatitis, HBV DNA levels are high, antibody to hepatitis B e antigen (anti-HBe) is detected, and liver disease may be severe. Sporadic cases and outbreaks of fulminant HBV infection have been attributed to precore mutants. Mutations in the S or pre-S gene, which encode envelope protein, have been reported in patients infected after vaccination and in individuals who received monoclonal antibody to HBV after liver transplantation. This variant contains a missense mutation in the surface antigen. Subsequently, these mutants were demonstrated in chronic HBV carriers even without these immune pressures. This mutation causes an infection in which HBsAg is undetectable but in which HBeAg and HBV-DNA are found, in contrast to the typical serologic pattern (see later discussion).

The role of X protein is not fully understood, but it is required for establishment of infection in vivo although not for transfection of cells in vitro.^{23,55} X protein is a regulatory protein involved in transcriptional activation during viral replication¹⁷²; it has also been shown to transactivate the promoters of other viruses, such as human immunodeficiency virus (HIV) and human T-lymphotropic virus type 1.²⁴⁷ In addition, the X protein appears to be involved in the development of HCC.¹⁹

Viral Life Cycle Overview

Viral binding and cell entry. Infection of the target cells begins at the plasma membrane of hepatocytes, where viral envelope proteins interact with specific cellular receptors (Fig. 157.2). While the identity of the receptors is unknown, the N-terminal region of the large envelope protein (pre-S1) appears to be essential and to mediate cell fusion interactions. Monoclonal antibodies to these proteins prevent infection and are a possible therapeutic strategy.¹⁴⁹ This process is thought to be triggered by low pH and/or proteolytic cleavage of envelope protein.¹⁹⁰

After uncoating/release into the cytoplasm and transport of the nucleocapsid to the nucleus, the partially double-stranded viral relaxed circular DNA (rcDNA) is repaired by both viral and cellular enzymes. Specifically, the incomplete plus-strand of the rcDNA is completed by the viral polymerase; in another step, the viral polymerase and ribonucleic acid (RNA)-primers used for DNA plus-strand synthesis are removed by cellular enzyme. In the nucleus, the genomic DNA is converted to a covalently closed circular DNA (cccDNA) form that serves as a template for reverse transcription.¹⁵² cccDNA's fundamental role is to act as a template for all viral RNAs and, consequently, progeny virion. This stable episomal plasmid-like molecule is the virologic key to the persistent reservoir of HBV that contributes to the difficulty in clearing HBsAg with currently available treatment even after prolonged treatment and the frequent rebound of viral replication upon withdrawal of DNA therapy or immunosuppression. A few copies of cccDNA per liver can (re)initiate full-blown infection and persist for the lifespan of the hepatocyte. A cure for chronic HBV requires elimination of cccDNA.²¹⁰

Genomic Replication

The first step in HBV genomic replication is the encapsidation of the genomic RNA template.²⁷⁷ Pregenomic RNA (pgRNA) is encapsidated together with the P protein.⁸⁶ Inside the nucleocapsid, pgRNA is reverse transcribed into negative-strand DNA. rcDNA is generated by plus-strand synthesis from negative-strand DNA. The nucleocapsids are either reimported to the nucleus for cccDNA amplification or enveloped and released via the endoplasmic reticulum (ER).

Viral Assembly and Release

The 20-nm subviral particles are assembled between the ER and Golgi apparatus.¹²⁵ These 20-nm particles contain predominantly S HBsAg

proteins, which are synthesized in the ER.¹⁰⁹ In addition, these particles may contain M subunits but generally do not have L HBsAg proteins.¹¹⁶ The assembly process is encoded totally in the S domain.¹⁶⁹ Assembled particles are transported through the secretory pathway and traverse the Golgi complex.^{144,275} The S protein carries out the entire assembly process without the involvement of other viral proteins.⁴ Therefore, subviral particles containing only envelope proteins are released. In vitro studies have shown that overexpression of L proteins gives rise to filamentous viral particles in the ER.⁶⁰ The overabundance of L, M, and S aggregates apparently is cytopathic to hepatocytes in vitro. Similar cytopathic features have been seen in human infections with HBV, yet the role of envelope protein expression in hepatocyte injury remains to be determined.⁴

The assembly of the Dane particle differs from the assembly of the 20-nm particles in that all three proteins—L, M, and S—are present.¹¹⁶ Studies of HepG2 cell lines transfected with HBV mutants have shown that no virus budding occurs if the envelope proteins are not present (mutations in S) and that for virion formation and release, both L and S proteins are needed.³⁶ M proteins apparently are not necessary for viral assembly.

Immunopathogenesis

HBV is not directly cytopathic, and the variability in liver damage is due to host immune responses. Although HBV preferentially infects hepatocytes and replicates therein, it can infect other liver cells, such as cholangiocytes, as well as cells in extrahepatic tissue, such as peripheral blood lymphocytes, pancreatic acinar cells, cornea, spleen, thyroid gland, kidney, adrenal gland, and smooth muscle.^{13,331}

Responses to HBV infection and the likelihood of developing chronic infection are dependent on both age at the time of acquisition and immune competence. Of infants born to mothers who are HBeAg positive, 90% become chronically infected with HBV compared with only 5% of those infected as adults. The production of antibodies to pre-S and S antigens by B cells, as well as cytotoxic T-lymphocyte (CTL) responses, mediates recovery from acute HBV infection. Individuals who clear HBV have a strong polyclonal human leukocyte antigen class I-restricted CTL response to multiple epitopes in the HBV envelope, nucleocapsid, and polymerase regions. This CTL response can be reactivated many years after clearance of all detectable evidence of HBV infection.¹⁸⁴

FIG. 157.2 Hepatitis B (HBV) virus infectious cycle. HBsAg, Hepatitis B surface antigen. (From Wells JT, Perillo R. Hepatitis B. In: Feldman M, Friedman LS, Brandt LJ, eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 10th ed. Philadelphia: Elsevier; 2016.)

Infants infected perinatally are at the highest risk for development of chronic HBV infection. During childhood, those infected as neonates characteristically have high circulating levels of HBV DNA but low disease activity, with very low rates of HBeAg seroconversion, either spontaneously or after treatment with IFN.¹⁸⁴ Researchers have offered numerous hypotheses as to why immune tolerance develops in neonates. One theory proposes that transplacental passage of HBeAg induces CD4⁺ anergy and, therefore, no CTL responses to HBeAg develop. However, HBeAg-specific T-cell proliferation eventually is detected in those who subsequently seroconvert, rendering clonal deletion an unlikely mechanism.¹⁸⁴

The development of chronic infection is either a failure of host immune responses or a testament to the ability of HBV to evade that response. As the virus replicates within hepatocytes, viral antigens appear on the cell surface. Subsequently, CTLs directed against HBeAg infiltrate the liver and cause hepatocyte necrosis.⁷⁵ In addition, HBV interferes with the production of cytokines of the Th1 response, especially IFNs that would otherwise elicit class II major histocompatibility complex antigen expression and enhance viral clearance. For reasons not fully understood, both the HBV-specific CTL response and the CD4⁺ helper T-cell response are weak in chronic HBV infection. The high HBV viral load may lead to depletion of peripheral T-cell responses.⁹⁴ However, HBeAg—produced in large amounts in chronic HBV infection—and HBsAg share T-cell epitopes. HBeAg may enter the thymus and induce immune tolerance to both HBsAg and HBeAg by decreasing the production of HBV-specific cytotoxic T lymphocytes. However, these cells can be reactivated in patients who undergo a spontaneous or IFN-induced HBeAg seroconversion.²⁴¹ Soluble HBeAg may itself contribute to persistence of HBV; there is some evidence that HBeAg favors production of T-helper–cell type 2 cytokines rather than T-helper–cell type 1 cytokines, which have a greater role in noncytolytic control of HBV.⁹⁴

Fulminant hepatitis is seen in less than 1% of infected individuals and has a high mortality rate. It is characterized by a brisk immune response and viral clearance. Those who survive will clear HBV and do not develop chronic HBV infection. A higher incidence of fulminant hepatitis occurs in those patients infected with HBV mutants that do not produce the HBeAg, suggesting either an increased rate of replication or lack of immune detection of the mutant HBV.¹⁵⁶

Epidemiology and Transmission

Although HBV occurs throughout the world, marked geographic differences exist, with highest endemicity levels in sub-Saharan Africa and prevalence below 2% in regions such as tropical and Central Latin America, North America, and Western Europe (Fig. 157.3).²²²

Areas of high, intermediate, and low endemicity, as reflected by carrier status, have been identified. Highly endemic areas are those where more than 8% of the population is infected. Examples include Southeast Asia, Africa, Commonwealth of Independent States, and China. More than 70% of the world's population lives in these high-endemicity areas. The Middle East, Central and South America, and parts of Eastern Europe are examples of intermediate-endemicity regions, where infection is found in 2% to 7% of the population. The United States, Australia, and Western Europe are areas of low endemicity, with chronic infection rates of less than 2% of the total population.²⁹⁹ In countries where HBV infection is highly endemic, perinatal or vertical transmission is very common. In areas of low endemicity, acute infections occur more commonly in adults, which, although causing significant morbidity, are less likely to result in chronic carriage than are asymptomatic infections in children.

In the United States, the prevalence of chronic HBV infection (HBsAg positive) among the general population was 0.27% from 1999 to 2006. During this time, 4.7% of the US population had evidence of either past or chronic infection with HBV.³⁰⁷ The most recent National Health and Nutrition Examination Survey (NHANES) covering 2007 to 2012 reports a stable overall prevalence of 0.3% in the United States. Since 1999, an estimated 10.8 million people have been infected with HBV.²⁴⁵

The rates among ethnic groups vary, with non-Hispanic blacks having the highest rates (12.2%) compared with non-Hispanic whites (2.8%) and Mexican Americans (2.9%). The prevalence rate of chronic HBV infection was higher among foreign-born children (0.89%) than US-born children (0.16%).³⁰⁷

HBV may be transmitted vertically, horizontally, parenterally, or sexually. Vertical transmission of HBV occurs in the perinatal setting when an infected mother transmits the infection to her child. If a mother is seropositive for both HBeAg and HBsAg, the risk for transmission of HBV to her child is 85% to 90% without immunoprophylaxis.¹⁴

FIG. 157.3 Global prevalence of hepatitis B virus infection among adults. (From Centers for Disease Control and Prevention. Infectious diseases related to travel. Available at: <http://wwwnc.cdc.gov/travel/yellowbook/2016/infectious-diseases-related-to-travel/hepatitis-b>.)

Horizontal transmission occurs among children in groups with moderate to high endemicity⁸³ who were not infected at birth.

The most common risk factors for acquisition of acute HBV in adults in the United States were heterosexual exposure or having multiple sexual partners (27%), intravenous drug use (18%), men who have sex with men (13%), household contact (3.6%), and occupational exposure (16%).¹⁰⁶ Approximately one-third of people reported no risk factors during the study period.¹⁰⁶

Within the United States, the number of reported cases of acute hepatitis B decreased 81% between 1990 and 2006 to the lowest rate ever recorded (0.9 per 100,000 population).³⁰⁶ Hepatitis B elimination strategies—such as screening of pregnant women, universal immunization of infants, and catch-up immunization of older children—are credited with the reduced incidence in children.

The experience from Taiwan, the first country to implement mass vaccination against HBV, is encouraging. Since 1986, all neonates have been vaccinated against HBV. Seroprevalence of HBsAg declined from 9.8% before this strategy to 0.6% 20 years later.²¹¹ There was a significant decrease in the incidence of HCC, from 0.54 to 0.20 per 100,000 children, between 1986 and 2000, and the proportion of infants and children with hepatitis B as a cause of fulminant hepatic failure in Taiwan decreased from 82% before mass vaccination to 57%.⁵³

Researchers have estimated that only 45% of the expected 20,000 HBsAg-positive women giving birth in the United States between 1993 and 1996 were identified.²⁶⁵ This low figure may be due to numerous factors; women likely to be infected often do not receive prenatal care²⁶³ or women may be tested but the information not conveyed to the place of birth or to the pediatrician caring for the child.¹⁴ Attention to this aspect of care is extremely important because the reduction in rate of transmission from mother to child with use of hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine is as high as 90%.²⁷⁴ HBsAg can be found in the breast milk of HBV-infected mothers. However, in studies performed in Taiwan and England, breastfeeding by HBsAg-seropositive mothers did not significantly increase the risk for neonatal acquisition of HBV infection.²³⁰ A study of 230 infants in China demonstrated that breastfed infants had similar response rates to HBV vaccination and failure rates to HBV immunoprophylaxis as bottle-fed infants.³⁰⁵ Effective immunoprophylaxis should allow for safe breastfeeding.

Natural History

Individuals infected with HBV can develop acute or chronic infection. Acute HBV infection is most common in young men older than 19 years and women older than 40 years,^{78,106} but most do not develop chronic disease. Children infected perinatally rarely develop acute hepatitis, but fulminant hepatic failure has been reported, particularly in infants born to HBeAg-negative mothers.⁵³ The clinical and serologic findings of chronic hepatitis B are shown in Fig. 157.4.

After infection with HBV, most patients either develop immunity and clear the infection or become chronic carriers. A lower percentage

will develop liver disease or chronic active hepatitis with an increased risk of developing cirrhosis, liver cancer, or both. Chronic HBV infection progresses nonlinearly through four phases (Fig. 157.5): immune-tolerant phase (high viral load, normal alanine transaminase [ALT]), immune-clearance phase (elevated viral load and ALT), inactive chronic carrier phase (low viral load, normal ALT), and reactivation of viral replication, which is observed only rarely. However, interplay among stages differs among patient groups.

The risk for acquiring chronic hepatitis B is related to a number of factors, such as very young age, other medical conditions, and other infections. The likelihood of progression to chronic infection is inversely related to age at the time of infection (Fig. 157.6). Approximately 90% of infants infected perinatally become chronic carriers unless vaccinated at birth. The risk for chronic HBV infection decreases to 30% of children infected between ages 1 and 4 years and to less than 5% of persons infected as adults. If an infected person has other medical problems, such as end-stage renal disease requiring hemodialysis, or is coinfecting with HIV, the risk for development of chronic HBV infection increases. The risk for development of HCC is increased in all HBV chronic carriers but especially those with active viral replication.¹⁷ Four of 99 children in an Italian study had HBeAg-positive cirrhosis; after 14.5 ± 6.1 years of follow-up, two developed HCC and two had lost histopathologic features of cirrhosis.^{31,33}

Most Chinese children, in whom chronic HBV usually is perinatally acquired, remain HBeAg positive, with very high levels of viral replication yet only minimal clinical liver disease.^{182,183} In contrast, children in the West with chronic HBV infection frequently clear HBeAg and HBV DNA from serum during the first 2 decades.³² In extended follow-up of the Italian study above, of 89 children who cleared HBeAg, four experienced reactivation, three of whom had HBeAg-negative hepatitis.³³ Those who lost HBeAg tend to have higher ALT levels early in life, indicating more active liver disease. Some of the children (15.4%) became seronegative for HBsAg as well.³³

Children born to Asian and Afro-Caribbean mothers in the United Kingdom who acquired HBV infection perinatally had a much lower (29%) rate of HBeAg seroconversion than white children in the U.K. study (80%)³⁴ or Italy (98%).³³ These differences are ascribed to the older age at acquisition of HBV in Western children which is associated with a more efficient immune response. These observations influence the management and counseling of children with chronic HBV infection as well as the design and interpretation of therapeutic trials.

Extrahepatic manifestations of both acute and chronic HBV infection occur more commonly in adults. Up to 25% of adults with acute HBV infection have extrahepatic manifestations, such as arthralgia and even serum-like sickness. Vasculitides can develop in both acute and chronic HBV infections; examples include polyarteritis nodosa, renal disease, and mononeuritis.²⁰² Membranoproliferative glomerulonephritis is an extrahepatic manifestation of chronic HBV infection in some children.^{148,272} There is a case report of epididymitis related to acute hepatitis B in a 12-year-old boy.²⁸⁴

Carcinogenesis

HCC is a recognized sequela of chronic infection with HBV; worldwide, most cases of HCC are linked to HBV infection. In Taiwan, the incidence of HCC in chronically infected individuals was 200 to 812 cases per 100,000 person-years compared with 10 to 30 cases per 100,000 person-years in the general population. In those with liver cirrhosis secondary to chronic HBV infection, the incidence increased to 1000 to 5000 cases per 100,000 person-years (1–5% per year).⁵⁴ Prior to effective therapies, the lifetime risk for development of HCC in a chronically infected person was estimated at 40% to 50%.¹⁷ The incidence of HCC is associated with serum HBV DNA levels in a dose-response relationship.⁵⁹ The risk for HCC after treatment is not clear; most treated individuals remain HBsAg positive and remain at some risk.

The detection of integrated HBV sequences in both human HCC and animal models has led to numerous theories regarding the mechanisms leading to HCC. Current hypotheses center on the integration of viral DNA into host genome, which may be associated with activation of oncogenes, deactivation of tumor suppressor genes, or other genetic instability. The finding that HCC cells in an infected individual contain

FIG. 157.5 Phases of chronic hepatitis B virus (HBV) infection: immune tolerant phase (high viral load, normal alanine aminotransferase [ALT]), immunoclearance phase (elevated viral load and ALT), inactive chronic carrier phase (low viral load, normal ALT), and reactivation of viral replication. CH, Chronic hepatitis; HBeAg, hepatitis B envelope antigen. (From Gish RG. Diagnosis of chronic hepatitis B and the implications of viral variants and mutations. *Am J Med.* 2008;121[12 Suppl]:S12–S21.)

FIG. 157.6 Outcome of hepatitis B virus infection by age at infection.

HBV DNA in discrete rather than random sites, indicating clonal expansion of tumor cells, supports this theory.²³⁶ The frequency and significance of integration of viral DNA into the host genome are unresolved issues in childhood HBV infection; some studies have shown early integration, whereas others describe it as a rare event.^{15,49,107,257,310} HBsAg loss has been associated with decreased risk of HCC, particularly if it occurs before the development of cirrhosis. Recent studies showed that high levels of HBV viremia are associated with an increased risk of cirrhosis, HCC, and liver-related mortality. Genotype of HBV may be an indirect marker of HCC risk. Genotype C with TCC at codon 15 of the precore region is associated with an increased risk for HCC in a Hong Kong population with cirrhosis.⁴³

Prevention of HBV infection and eradication of existing infection remain the most effective measures to prevent HCC. After a nationwide hepatitis B vaccination program implemented in Taiwan in 1984, there was a significant decrease in the incidence of HCC, from 0.54 to 0.23 per 100,000 children between 1986 and 2000.^{47,211} A recent review of 1509 patients age 6 to 26 years from two Taiwan HCC registries diagnosed with HCC from 1983 to 2011 demonstrated a significant difference in incidence of HCC among vaccinated and unvaccinated cohorts: 0.23

and 0.92 per 100,000 people, respectively.⁵¹ Incomplete immunization was the most important risk predictor of HCC among vaccinated infants.^{48,53} The 5-year survival rate in children with HCC is less than 30% despite treatment.³²¹

The age at which surveillance for HCC should commence and the optimal frequency have not been determined.¹⁸⁶ Although HCC is detected most often after at least 20 years of chronic HBV infection, cases in children as young as 8 months old have been reported.^{103,283,314} Childhood HCC associated with HBV infection has been described in both Asian^{52,283} and Western^{103,232} populations. Because most cases are reported retrospectively, data regarding incidence are not available. No guidelines have been developed for prospective monitoring of children with chronic HBV infection for development of HCC, although periodic measurement of serum α -fetoprotein levels combined with hepatic ultrasound evaluations are recommended in adults.

Histopathologic Features

The purposes of obtaining a liver biopsy in chronic HBV infection are to quantify the severity of fibrosis, to rule out other causes of liver disease, and to monitor disease severity after treatment. In typical acute viral hepatitis, a liver biopsy usually is not required or indicated. If performed, the findings are liver cell degeneration and necrosis, with lobular disarray. The acute injury to hepatocytes is manifested as both ballooning and acidophilic degeneration, either of which can resolve or progress to cell death. Inflammatory cell infiltration and liver cell regeneration are also seen.¹²¹

The histopathologic changes of chronic HBV infection are characterized by portal tract inflammation, interface hepatitis, and fibrosis, which may progress to architectural distortion of lobules and eventual cirrhosis (see Fig. 157.7).¹²¹ Chronic HBV infection is characterized by “ground glass” cells, which are hepatocytes containing HBsAg and most easily identified by staining with orcein, Victoria blue, or aldehyde fuchsin. However, these cells also are found in other liver diseases, and the pattern of staining is important. In hepatitis B, ground glass cells are found either singly or in clusters arranged in a haphazard pattern. “Sanded” liver nuclei are caused by accumulation of HBcAg and generally are identified by electron microscopy¹²⁷ or immunoperoxidase techniques (see Fig. 157.7).

Histopathologic staging and grading systems are used to allow standardization and meaningful comparisons in chronic hepatitis. One such system is the Knodell-Ishak score, which evaluates four

FIG. 157.7 Liver histology in hepatitis B infection. (A) Core antigen (HBcAg) immunohistochemical stain demonstrating nuclear staining of scattered hepatocytes at $\times 40$. (B) Scattered hepatocytes with ground glass, finely granular cytoplasmic inclusions with focal displacement of the nucleus to the periphery at $\times 40$. (C) Portal tracts with moderate lymphoplasmacytic inflammation and minimal interface activity at $\times 20$. Occasional hepatocytes show ground glass, finely granular cytoplasmic inclusions. (D) Hepatitis B surface antigen (HBsAg) immunohistochemical stain shows occasional hepatocytes with cytoplasmic staining at $\times 40$.

histopathologic features, each scored using specific criteria.¹⁵⁰ This system has proved reproducible, is now in common use, and is also known as the modified histologic activity. Other systems are the Batts-Ludwig¹⁶ system and the METAVIR system, which categorizes liver fibrosis into 4 stages (F0, no fibrosis; F1, portal fibrosis without septa [mild]; F2, portal fibrosis with few septa [moderate]; F3, numerous septa without cirrhosis [severe]; and F4, cirrhosis).²⁵⁰ The systematic classifications are useful in estimating progression of disease and response to therapy and for comparing outcomes in therapeutic trials. More recent studies of patients with chronic HBV showed improvement and even reversal of hepatic fibrosis¹⁵⁷ and histologic activity index after treatment with antivirals.

Biomarkers

The rapid onset of liver disease in some children (i.e., HBV, genotype C) indicates a need to identify early markers of liver fibrosis to help facilitate early intervention. Serum chemistries used to assess hepatic inflammation and injury are not reliable. Empirically identified markers identified by genomic, proteomic, and metabolomic technologies, as well as targeted serum marker analysis, offer new strategies with which to diagnose and predict outcomes in pediatric liver diseases.^{92,218,225,270} Preliminary studies in children with fibrotic liver diseases have identified specific markers reflecting matrix remodeling, hepatic stellate cell

activation, and chemoattractant expression in this age group.^{218–220,270} Collagen markers and micro-RNA are also among the biomarkers of fibrosis being investigated for viral hepatitis.

No single marker has yet proven useful in children with chronic HBV infection, but serum noninvasive models using a combination of serum markers and enzyme immunoassays to predict hepatic fibrosis have been studied in adults and children with viral hepatitis with promising results.^{171,238} Fibrotest (Biopredictive), which includes alpha2-microglobulin, haptoglobin, gamma-glutamyl peptidase, total bilirubin, ALT, and apolipoprotein A1 to provide a score of 0 to 1, with a conversion to the stages of fibrosis has been widely studied and proven to be a good biomarker for fibrosis^{74,233} in viral hepatitis. The Enhanced Liver Fibrosis (ELF) test (Siemens Healthcare Diagnostics Inc.) is another panel of biomarkers comprised of hyaluronic acid, tissue inhibitor of matrix metalloproteinase-1, and aminoterminal propeptide of procollagen type III, derived from studies in patients with a range of chronic liver diseases including chronic hepatitis B.²⁴⁶ A study looking at ELF in a cohort of 182 patients with chronic hepatitis B who underwent liver biopsies showed areas under the receiver operating characteristic curve (AUROC) of 0.77, 0.82, 0.80, and 0.83 for detecting METAVIR fibrosis stages $F \geq 1$, $F \geq 2$, $F \geq 3$, and F4, respectively, suggesting that ELF has good performance in detection of liver fibrosis in patients with chronic hepatitis B.²⁹¹

Aspartate aminotransferase (AST)-platelet ratio index (APRI) and fibrosis index based on the four-factor (platelets, ALT, AST, and age) fibrosis-4 (FIB-4) calculation are the most useful serum biomarkers in identifying advanced or severe liver fibrosis in patients with chronic hepatitis C.^{110,259,297} However, their clinical utilities in patients with chronic hepatitis B have been controversial.^{40,258,286,292,304,320} Recent studies have shown APRI and FIB-4 to be useful for the diagnosis of fibrosis, with similar accuracy in predicting significant and severe fibrosis.

For prediction of significant fibrosis, severe fibrosis, and cirrhosis, the AUROCs of FIB-4 were 0.646, 0.670, and 0.715, respectively, and 0.656, 0.653, and 0.639, respectively, for APRI in a 2016 study looking at 1543 consecutive chronic hepatitis B patients who underwent liver biopsies from 2006 to 2010. Further subgroup analysis demonstrated that the diagnostic accuracy of FIB-4 and APRI in patients with normal ALT was higher than that in patients with elevated ALT.³²⁸ A systematic review and meta-analysis in 2015 showed that APRI and FIB-4 can identify hepatitis B–related fibrosis with moderate sensitivity and accuracy in adult patients.³¹⁵ In children with chronic hepatitis B, APRI has also been shown to be an accurate, inexpensive, and simple noninvasive index in predicting advanced liver fibrosis.^{71,200}

Imaging

Other noninvasive techniques studied in adults and children include transient elastography, shear wave elastography (SWE), and acoustic radiation force impulse (ARFI).¹⁸ These modalities appear promising in identifying patients with normal or near-normal ALT but significant fibrosis who might benefit from therapy.¹⁴⁶

Traditional gray-scale ultrasound imaging (sonography) uses high-frequency sound waves to view soft tissues and organs and is an excellent modality for the pediatric population, limiting the use of radiation. However, conventional ultrasound is limited by operator experience and technique, interpretation bias, and by the inability to differentiate between liver steatosis and fibrosis, a particularly important distinction given the childhood obesity epidemic.^{57,104} Furthermore, a noninvasive imaging modality that can differentiate between mild and moderate fibrosis (i.e., F1/F2 vs. F2/F3) has not yet been validated in pediatric viral hepatitis.

The complementary noninvasive ultrasound advancement, elastography, measures the inherent elasticity of the liver, which may be altered by pathologic processes such as inflammation, tumor, and, importantly, fibrosis.^{38,217,319} Elastography has the ability to assess small changes in pliability of liver tissue across the entire liver. Elasticity of tissue in the context of elastography is the ratio of tension (stress) needed to produce a relative change in length (strain) and quantifies how much pressure must be placed on tissue in order to cause elastic deformation.^{45,282} Two types of elastography are widely used in imaging, transient elastography (TE) and SWE. TE—that is, FibroScan (EchoSens)—requires mild compression with the ultrasound transducer with some limitations gaining access to the liver due to overlying ribs. SWE is a reproducible technology that assesses tissue stiffness by measuring the speed of a shear wave through tissue, measured in units of speed in the United States and pressure (kilopascals) in Europe, neutralizing operator variability. Recent publications have reported that SWE is more accurate than TE in the detection of significant liver fibrosis (greater than F2). Similarly, ARFI imaging allows for the assessment of tissue stiffness by evaluating the wave propagation speed²⁰⁴ using a conventional probe without the need for external compression, which reduces operator dependency. The generated wave scan provides qualitative (imaging by Virtual Touch Tissue Imaging; Siemens) or quantitative (wave velocity values, measured in m/s using Virtual Touch Tissue Quantification; Siemens) responses. Studies comparing TE and ARFI demonstrate that both methods yield reliable assessment of liver fibrosis. ARFI is being used with promising results in studies to evaluate liver fibrosis in children with diffuse liver diseases and biliary atresia before and after transplantation.^{114,115}

Normal values of SWE and ARFI have been established for the liver and other organs in the body, showing much promise as a tool to distinguish normal from abnormal tissue in adults and children.^{10,97,113}

Elastography and ARFI allow for a more global assessment of liver fibrosis than a single core of liver tissue and are being used to detect

hepatic fibrosis in adults with viral hepatitis^{5,93,108} but not yet in children.

Treatment

Most patients with acute HBV infection recover fully and develop permanent immunity (anti-HBs), and treatment is purely supportive. The role of antiviral therapy in fulminant HBV infection has not been studied systematically. Treatment, when indicated, is directed at those with chronic HBV infection. In this setting, the long-term goals of therapy are eradication of HBV and reduction of cirrhosis, development of HCC, and mortality. Intermediate goals for treatment include HBeAg seroconversion, suppression of HBV DNA to undetectable levels, and normalization of aminotransferase values. Clearance of HBsAg is considered a functional cure.

To date, no agents completely fulfill all of these goals in either adults or children, but significant progress has been made. Children and adults have differences in immune tolerance and rate of progression of liver disease. Therefore, studies of treatments of chronic HBV in adults cannot be extrapolated directly to children. In addition, the timing and choice of therapeutic agent are crucial because of differences in age, maturity, stage in natural history, and comorbidities.

A child being considered for treatment should have serologic evidence of chronic HBV infection, such as HBsAg for at least 6 months, as well as evidence of active HBV replication, HBeAg, or HBV DNA (in the case of eAg-negative HBV infection). In addition, children with consistent ALT elevation of at least twice the upper limit of normal or active disease on liver biopsy are more likely to benefit from treatment. Because therapy may be indefinite, a liver biopsy should be considered before the start of therapy to provide evidence of chronic hepatitis, to stage the disease, and to rule out other processes.

In most studies performed before the high prevalence of HBeAg-negative infections, seroconversion from HBeAg to anti-HBe in serum was used as the primary outcome variable for response to therapy. Therapeutic trial results must be compared with the “background rate” of spontaneous conversion from HBeAg positive to anti-HBe, which in children younger than 3 years is very low (<2% per year) but increase with age so that in children older than 6 years, the yearly clearance rates vary from 14.3% to 35.3%.⁴⁶

Quantitative HBsAg and quantitative HBeAg are being investigated as predictors for treatment responses. Varying levels of quantitative HBsAg have been documented over the natural course of HBV infection and among different genotypes.¹²⁹ Levels of HBsAg decrease with increasing age and progression of disease with increased fibrosis.¹²⁸ These values may be helpful in determining treatment strategies and algorithms for stopping therapy.^{44,173}

First-line antiviral treatment options for HBV-infected children include IFN- α and the nucleos(t)ide analogs entecavir and tenofovir. In the United States, interferon (IFN- α) is approved for children after the age of 1 year and lamivudine and entecavir after 2 years. Adefovir and tenofovir have been approved for use in children 12 years and older. IFN, lamivudine, and adefovir are no longer recommended first-line treatments for adults with HBV due to availability of other agents with better side effect profile and resistance rate. Clinical trials using pegylated IFN- α 2a and tenofovir in children with chronic HBV are under way.

Interferon

IFNs are a family of cytokines with immunomodulatory, antiproliferative, and direct antiviral actions. IFN induces the display of human leukocyte antigen class I molecules on hepatocyte membranes, which, in turn, promotes lysis by CD8⁺ cytotoxic lymphocytes. At the same time, it directly inhibits viral protein synthesis.¹⁷² IFN- α has been the primary form used in the treatment of chronic HBV infection; IFN- α 2a and IFN- α 2b have been licensed in the United States for use in children. Peginterferon- α , in which the IFN molecule is attached to polyethylene glycol to allow for once weekly versus three times weekly injections, is the preferred form in adults but has not yet been approved in the United States for children with chronic HBV. Clinical trials of a combination of pegylated IFN plus entecavir in children with immune-tolerant chronic HBV are under way.

Loss of HBV DNA or development of HBeAg seroconversion was achieved with IFN- α treatment in 20% to 58% (compared to 8–17% in the control group) of European and 3% to 17% of Asian children in early studies.^{164,296} The difference may be due to higher rates of perinatally acquired infections in the Asian countries studied. A large multinational, randomized control led trial of IFN- α 2b later showed similar loss of HBsAg between children born in Asian countries (22%) and those from Europe and North America (26%) if aminotransferase values were elevated.²⁶⁷ Ten percent of treated adults and children lose HBsAg, compared with 1% of untreated patients.^{155,267} Long-term (1.1–11.5 years) follow-up of adult responders to IFN- α showed a significantly reduced incidence of HCC compared with either treated nonresponders or untreated control patients.¹⁷⁹ The long-term outlook for treated children is not yet clear. In a Turkish study, none of the 23 treatment nonresponders developed cirrhosis or HCC at a mean follow-up of 4.5 years.¹⁵¹ A second study compared long-term (5.6 ± 3.1 years) outcome in two groups of 37 children: one group was treated with IFN- α 2 β and the second control group of children age matched for age, sex, and baseline ALT level received no treatment. At time of follow-up, the rates of HBeAg and HBsAg loss were 54.1% (20/37) and 8.1% (3/37) in treated children compared with 35.1% (13/37) and 2.7% (1/37), respectively, in untreated children (not significant). Histologic outcomes in children with chronic HBV treated with IFN- α for 20 weeks have been reported in 93 children, average age 7.1 years, in Poland. Liver biopsy samples were obtained before treatment and 12 months after the end of the treatment and graded for fibrosis and inflammation using three different scoring systems. Over a third of children underwent HBeAg/anti-HBe seroconversion. Liver fibrosis did not improve regardless of responder status, but inflammatory activity was decreased after treatment in both responders and nonresponders.³¹² Two meta-analyses of treatment of chronic HBV in children with IFN- α have been conducted. Each concludes that treatment leads to a higher rate of HBeAg seroconversion than would occur spontaneously.^{290,295} Unfortunately, two-thirds of children treated with IFN- α show no sustained response to therapy.

Children with evidence of active immunologic responses to HBV (i.e., low/high alternation levels of viral replication [HBV DNA]) and high ALT values (greater than twice normal) are more likely to have a response to therapy with IFN- α .²⁹⁰ A study from Sweden demonstrated that pretreatment HBV DNA levels were associated with sustained virologic response.²⁶⁶ Children who acquired disease by vertical transmission are more likely to have established immune tolerance and may be less likely to respond to treatment. Children with very low HBV DNA levels may be in the process of spontaneous seroconversion; therefore, an expectant policy may be prudent.

Side effects of IFN- α include a transient influenza-like syndrome (fever, myalgia, headache, arthralgia, and anorexia) that occurs in virtually all patients at the start of therapy. Bone marrow suppression, especially neutropenia, is a common side effect, seen in 39% of children in one series.¹²⁶ Changes in personality, irritability, and temper tantrums are reported more frequently in children than in adults and may interfere with compliance.^{126,267} These problems resolve once treatment is withdrawn. Febrile seizures and marked elevation of aminotransferase levels have also been reported. Quality of life is impaired in children during IFN therapy compared with their pretreatment levels because of medication side effects and fear of injections. However, within 3 months of cessation of treatment, these effects are reversed.¹²⁶

HBV Polymerase Inhibitors

This class of agents includes the nucleoside and nucleotide analogs that inhibit HBV polymerase by incorporation into viral DNA, leading to termination. They are administered orally and generally well tolerated¹⁸⁹ and presented in the order they were approved by the US Food and Drug Administration.

Lamivudine

Lamivudine (2',3'-dideoxycytosine), also known as 3TC, is an oral nucleoside analog. It is triphosphorylated intracellularly to an active intermediate that is incorporated into the growing DNA chain, thereby terminating the chain and inhibiting viral replication.

There are a number of large randomized studies demonstrating benefit of lamivudine in children and adults.^{79,163} Treatment with lamivudine achieved clearance of HBV DNA and HBeAg in 23% compared with 13% in the placebo group ($P < .05$). However, 19% of the treatment group developed the primary mutation associated with lamivudine resistance (i.e., tyrosine-methionine-aspartate-aspartate) in the first 48 weeks of therapy. Higher response rates were observed in those with positive HBeAg and higher ALT levels, as had been noted with IFN.²¹² Longer duration of treatment (3 years) improved response rate but also showed increased development of resistant mutants (up to 58%). Mutations induced by lamivudine often confer resistance to the newer antiviral agents. The virologic response to those with the tyrosine-methionine-aspartate-aspartate variant was only 5% (5/100) compared with 49% (34/70) in those with wild-type HBV.²⁶⁹ The use of lamivudine has largely been replaced in adult HBV treatment by newer agents with more favorable resistance profiles. The same has been true within pediatrics. While no longer considered a first-line treatment option, lamivudine has utility in the prevention of vertical transmission of HBV in developing countries and may be considered in restricted circumstances.

No serious side effects of lamivudine were reported. However, lamivudine is excreted by the kidneys, and use in patients with renal failure requires dose reduction. On cessation of therapy, patients need to be monitored for the occurrence of "lamivudine withdrawal flare" presenting with elevation of serum ALT of up to three times baseline (as compared with 8% of placebo-treated patients) possibly progressing to jaundice and incipient liver failure.¹¹⁹

Studies of combination therapy with IFN- α and lamivudine have been performed in both children and adults. In adults with HBeAg-positive chronic HBV, peginterferon- α 2a either alone or in combination with lamivudine for 48 weeks was superior to lamivudine alone, achieving HBeAg seroconversion, normalization of ALT, and HBV DNA suppression in 21% compared with 23% of those who received peginterferon plus placebo and 10% who received lamivudine alone.¹⁶⁸ A complete response rate of 34% has been reported in children on combination therapy.^{7,162}

Adefovir Dipivoxil

Adefovir dipivoxil (ADV) is a synthetic nucleotide analog of adenosine monophosphate³²⁶ that was first approved in 2002 but is no longer considered first-line therapy for HBV infection. Previous studies have demonstrated efficacy in patients with HBeAg-positive and HBeAg-negative chronic HBV infection, showing significant virologic, biochemical, and histologic improvement after 48 weeks of treatment in adults and children.^{112,134} A study of ADV in 173 children with HBeAg-positive chronic hepatitis B showed that 23% of children aged 12 to 18 years were able to achieve a normal ALT and HBV DNA less than 1000 copies/mL compared with no subjects treated with placebo.¹³⁴ However, approximately 30% of patients display primary nonresponse to ADV, defined as a less than 2log₁₀ drop in serum HBV DNA after 6 months of treatment.

Various mutations (including N236T and A181V) have already been described to confer resistance to ADV, with resistance rates up to 29% after 5 years of treatment. Also of concern is that HBV isolates with N236T and A181V mutations in *in vitro* studies have decreased susceptibility to the newer agent tenofovir by 4-fold and 3.2-fold, respectively,^{181,298,302,332} making adefovir a less desirable treatment for HBV.

Tenofovir

While tenofovir disoproxil fumarate (TDF), a nucleotide analog reverse-transcriptase inhibitor, was approved for children more than 2 years when used as a component of antiretroviral therapy in 2001, it had only recently been approved in September 2012 for monotherapy of chronic HBV in children over 12 years of age in the United States. A randomized, placebo-controlled trial using tenofovir in adolescents demonstrated potent antiviral effects with acceptable safety. A total of 106 patients were enrolled to take either tenofovir 300 mg or placebo once daily for 72 weeks. Normalization of the ALT value occurred in 74% of patients taking tenofovir and 31% (relative risk [RR], 2; 95% CI, 1.4–2.9) of patients taking placebo with significantly higher HBV DNA suppression (RR, 92.4; 95% CI, 5.8–146.7).²⁰⁹ The study did not

show any evidence of TDF resistance at the end of 72 weeks, a significant advantage of TDF.²⁰⁹ This finding was also confirmed in adult open-label phase III studies in which 238 HBeAg-positive patients receiving TDF monotherapy were able to maintain effective suppression of HBV DNA through 288 weeks of treatment with no evidence of TDF resistance.¹⁴⁷ Furthermore, tenofovir appears to be an effective rescue therapy in chronic HBV patients who failed previous nucleoside analog treatments.¹⁵⁹ Baseline HBV DNA may be a significant predictive factor for a virologic response to TDF mono-rescue therapy for multidrug-resistant chronic HBV.¹⁷⁴

Adverse events were not common in either group, but TDF was associated with a small risk in decreased bone mineral density compared to placebo, especially in patients with HIV who are at risk for osteoporosis.^{207,209} Clinical trials to examine the safety and efficacy of TDF in children age 2 to less than 12 years as well as tenofovir alafenamide are currently under way ([ClinicalTrials.gov](#) NCT01651403).

Entecavir

Entecavir (ETV) is a cyclopentyl guanosine analog that inhibits HBV polymerase that was approved by the Food and Drug Administration for use in March 2014 to treat children age 2 years and older with chronic HBV. ETV for 48 weeks suppresses HBV DNA levels in both HBeAg-positive and HBeAg-negative adults at higher rates compared with lamivudine.^{120,133,136,185,187,311}

In one cohort study of 1980 adult patients with chronic HBV and cirrhosis followed for a mean of 52 months, ETV versus control reduced the risk of HCC (RR, 0.3; 95% CI, 0.1–0.5) and death (RR, 0.6; 95% CI, 0.3–0.98). A randomized control led trial comparing ETV versus placebo in 228 children with chronic HBV from North America, South America, Europe, and Asia demonstrated higher ALT normalization (RR, 2.9; 95% CI, 1.8–4.7), HBV DNA suppression (RR, 14.8; 95% CI, 3.7–58.3), and HBeAg seroconversion (RR, 2.4; 95% CI, 1.1–5.5) at 48 weeks. Longer duration of treatment (96 weeks) resulted in persistently statistically significant HBeAg seroconversion (RR, 1.8; 95% CI, 1.0–3.4). More recent studies of patients with chronic HBV treated with ETV showed improvement and even reversal of hepatic fibrosis.^{157,303} Long-term follow-up studies of ETV in children are forthcoming.

In children with baseline HBV DNA less than 8 log₁₀ IU/mL, the virologic response rates were similar between children (83%) and adults (79%). The virologic response was lower (28%) at 48 weeks when HBV DNA was greater than or equal to 8 log₁₀ IU/mL but increased to 64% with 96 weeks of ETV therapy. A 2016 report by Chang et al.⁵⁰ described nine children with chronic HBV treated with ETV at 0.015 mg/kg/day (maximum dose, 0.5 mg daily) for at least 52 weeks, five of whom (55.6%) demonstrated a complete viral response. These children had undetectable HBV DNA levels at 1 year after study entry, which was significantly higher than the control group (11.1%).

Furthermore, ETV has been shown to have low resistance rates in adults and children and is able to suppress both lamivudine-resistant and adefovir-resistant viruses, although a higher dose of the medication is indicated in the lamivudine experienced. In a randomized control led trial in children, ETV was well tolerated with no observed differences in adverse events or changes in growth compared with placebo.¹³² A clinical trial using combination pegylated IFN and ETV in children with chronic HBV is under way ([ClinicalTrials.gov](#) NCT01368497, Phase III).

Hepatitis B in Special Populations

Hepatitis B and Human Immunodeficiency Virus Coinfection

Although the prevalence varies from region to region, approximately 5% to 10% of HIV-infected adults worldwide also have chronic HBV infection. HIV/HBV coinfection in some sub-Saharan African populations is believed to be significantly higher.^{37,197,287} The prevalence of HBV infection among HIV-positive individuals is significantly higher than in HIV-negative individuals, an expected finding due to the common transmission routes (perinatal, horizontal, parenteral, sexual).^{6,195} The prevalence of HBV/HIV-coinfected pregnant women in Africa ranges from 0.4% to 7.1%. It is estimated that three million people from sub-Saharan Africa are coinfecting with HIV and HBV, many of whom may be immunotolerant children.^{234,248}

The prevalence and course of HBV infection in adults who are coinfecting with HIV have been examined in numerous studies. Of 181 HIV-infected adults in Greece, 71.8% of men who have sex with men and 91.7% of intravenous drug users had evidence of HBV infection.⁸¹ In a study from Australia conducted between 1985 and 1989, men with HIV infection were more likely to have chronic HBV infection than were HIV-negative men.²⁴ In Western Europe and the United States, among HIV-infected persons, 6% to 14% have chronic hepatitis B, including 4% to 6% of heterosexuals, 9% to 17% of men who have sex with men, and 7% to 10% of injection drug users.⁸ A recent study in Thailand found the prevalence of HBV coinfection in perinatally HIV-infected adolescents to be 3.3%.¹²

In HIV-positive patients—even those on combination antiretroviral therapy (cART), including lamivudine—low CD4 counts are associated with a higher rate of detectable HBV viremia.²⁷¹ Conversely, chronic HBV does not seem to alter the progression of HIV infection and does not influence HIV suppression or CD4 cell responses following cART. No evidence has been found for direct interaction between HBV and HIV. HIV/HBV-coinfecting individuals have higher circulating levels of HBV DNA but not worse hepatic necroinflammation.⁶⁶ In patients with HBV and HIV coinfection, there are higher rates of HBV persistence, HBV relapse (reemergence of HBsAg), and more severe and rapid progression of liver disease. Spontaneous HBeAg seroconversion rarely occurs in this group.

In adults with coinfection, the progress and complications from HBV hepatitis occur at an increased rate. Patients with HIV, especially those with a lower number of CD4 cells, are up to six times more likely to develop chronic hepatitis B after acquiring infection than those without HIV. Furthermore, coinfecting adults have more severe liver fibrosis with an increased risk of development of cirrhosis and end-stage liver disease in spite of evidence of less hepatic necroinflammatory pathology and lower ALTs.^{67,100,111,235,288,289} Follow-up of over 5000 adult men in the Multicenter AIDS Cohort Study for a mean of 10.5 years found that those coinfecting with HIV/HBV had an eightfold greater risk of mortality due to liver disease compared with those with HIV infection only and a 19-fold greater increase compared with those with HBV infection only. Immune reconstitution hepatitis can occur after initiation of cART, which may lead to anti-HBeAg seroconversion and loss of HBsAg or severe hepatic decompensation and death.^{85,199} Furthermore, patients with coinfection are at risk for HBV reactivation following withdrawal of cART, which includes HBV-active agents.⁸⁴

Limited longitudinal studies of HBV/HIV coinfection in children show that the mean HIV-1 RNA level was higher and the CD4 percentage was lower in children who had detectable HBV DNA levels, suggesting that children with more active HIV disease have less immune control of HBV. Adolescents with more severe immune suppression had higher levels of HBV DNA and were more likely to be HBsAg positive and have a significantly lower clearance rate.^{249,251} Extrapolating from adult data, there is concern that HBV/HIV-coinfecting children may have more active liver disease and progress more quickly to hepatic fibrosis and cirrhosis than monoinfected children.

HIV-infected children may be unprotected from HBV even after receiving the full three-dose immunization series, due to a less robust initial immunologic response and waning of anti-HBs antibody tiers.^{3,231,264} In a study conducted by the International Maternal Pediatric Adolescent AIDS Clinical Trials group, only 24% of 204 HIV-infected cART-treated children (median age, 9 years) with a history of previous immunization with three doses of HBV vaccine had protective anti-HBsAg antibody levels prior to receiving a booster vaccine. Forty-five percent of the children became seropositive 8 weeks after a booster vaccine. Vaccine response was greatest in those children with higher CD4 counts and undetectable viral loads. Lao-Araya et al.^{165,166} reported on 64 HIV-infected children (median age, 10 years) on cART for a median of 31 months with a previous history of routine infant HBV immunization. Eighty-seven percent had no measurable anti-HBsAg antibody prior to revaccination. The response rate to a repeat HBV immunization series was 17% after the first vaccine, 82.5% after the second, and 92% after the third. After 3 years, 71% of these children maintained protective anti-HBsAg antibody levels, suggesting that

HIV-infected children will benefit from a repeat HBV vaccine series after initiation of cART.

Extrapolating from data in adults, IFN- α may be less effective in coinfecting children, particularly in those with significant HIV-associated immune suppression. Nevertheless, IFN- α is the preferred treatment, particularly in younger children and in those who meet indications for HBV but not HIV treatment.^{80,143}

Lamivudine has an excellent safety profile for extended use in HIV- and HBV-infected children and is recommended as a part of a combination antiretroviral regimen for coinfecting children who require both HIV and HBV treatment. However, therapy with lamivudine as the only anti-HBV agent is problematic due to the high risk of development of HBV resistance mutations after prolonged therapy in monoinfected adults and children and in coinfecting adults with uncontrolled HBV viremia. Thus, lamivudine should not be used for treatment of HBV in coinfecting individuals in the absence of additional antiretroviral agents. Options for treating HIV/HBV-coinfecting children would be to initiate LMV-sparing cART in those who would not otherwise require HBV treatment or to include additional anti-HBV medications in the cART regimen.²⁰⁶

Adefovir has minimal anti-HIV activity. Therefore, it could be used in older coinfecting children who require HBV but not HIV treatment.¹³⁵ Several small studies in HIV/HBV-coinfecting adults failing previous anti-HBV treatment have similarly shown significant decreases in HBV DNA after the addition of ETV.^{226,239} While insufficiently potent to be considered an HIV therapy, entecavir has activity against HIV such that monotherapy ETV results in the development of the M184V mutation and should not be used as monotherapy in HIV-coinfecting individuals in the absence of additional antiretroviral agents.¹⁹⁹ Adult treatment guidelines recommend inclusion of tenofovir plus lamivudine in the antiretroviral therapy regimen for coinfecting adults who require treatment for HIV.^{35,143} Tenofovir has recently been labeled for treatment of HIV-infected children down to 2 years of age. As with lamivudine, tenofovir also has significant HIV activity and should not be used as a single agent in coinfecting individuals without additional antiretroviral agents.

Due to concerns of hepatic flares after initiating cART in coinfecting individuals, adult guidelines recommend that HBV-active agents be included in any cART regimen for coinfecting adults regardless of stage of HBV disease.¹⁴³ Specifically, tenofovir plus lamivudine or emtricitabine (another nucleos(t)ide analog not labeled for treatment of HBV) are recommended to decrease the risk of HBV mutations. However, up to 25% of HBV/HIV-coinfecting adults experience hepatic flares after starting cART.^{85,199}

Hepatitis B in Solid-Organ Transplant Recipients

Chronic HBV infection became a relative contraindication to liver transplantation after initial poor results. In the 1970s and 1980s, more than 80% of patients became reinfecting quickly, and 55% died within 60 days of surgery. Patients who had recurrence of HBV infection after liver transplantation (LT) developed a characteristic histologic lesion, termed *fibrosing cholestatic hepatitis*, which eventually led to loss of the allograft.²⁰ The term *de novo HBV infection* is defined as HBV infection occurring in HBsAg-negative liver recipients who become HBsAg positive after transplant. In a retrospective study of 71 HBsAg-negative Taiwanese children who received orthotopic LT, 15.3% of patients developed *de novo* HBV infection. In this study, higher HBsAb titers (>200 mIU/mL) were thought to be sufficient to possibly prevent *de novo* HBV infection in LT patients.²⁷⁶ The demonstration in the 1990s that HBIG is efficacious in decreasing infection of the allograft has allowed successful transplantation. The use of long-term HBIG decreases the risk for recurrence to 30% at 12 months and increases patient survival to greater than 90% at 12 months after transplantation.²⁵³ The allograft reinfection rate is even lower if the patient does not have active HBV replication at the time of transplantation. The cost of HBIG is a major factor, and duration of therapy appears to be lifelong to maintain protective HBs titer.

HBV infection is the fourth most common cause of acute liver failure in adults in the United States.²²¹ Rarely, however, does a child in the United States with HBV need a liver transplant for either acute or chronic liver failure.²⁷³ Of 215 children who underwent transplantation

between 1986 and 1992 at a major French center, only 4 had HBV-associated disease.¹⁹⁴

All patients with HBV-decompensated cirrhosis should be commenced on nucleos(t)ide analogs (NAs), regardless of viral load and ALT activity. Such patients should be selected for LT if they present hepatic dysfunction.^{61,208} The application of NAs prompted a new era for LT of HBV-decompensated cirrhotic patients, because they reduced the rates of recurrence remarkably and improved their prognosis dramatically (survival rates up to 90% over 5 years after LT).⁷³ All data suggest that an effective pretransplant anti-HBV therapy prevents posttransplant HBV recurrence.²²³ ETV administration in HBV-decompensated cirrhotic patients improved mortality. Those treated with ETV for 24 weeks had greater reduction in ALT levels and Model for End-Stage Liver Disease score compared to those on lamivudine.⁵⁶ In adults, ETV and tenofovir are the recommended first-line NAs in patients with HBV-decompensated cirrhosis.

After LT, HBV DNA of 20,000 IU/mL or greater and HBeAg positivity at the time of LT are associated with high risk of HBV recurrence, while HBV DNA clearance and fulminant HBV and hepatitis D virus coinfection pose less risk of HBV recurrence.¹⁶⁷ To date, the combination of an NA with a low dose of HBIG is the preferred therapeutic regimen.⁶²

Patients treated with HBIG and lamivudine had more frequent recurrence than those who received HBIG and adefovir. The combination of HBIG and ETV or TDF is the best prophylaxis, almost eliminating posttransplant HBV recurrence (<2%).⁶³

The course of HBV infection in heart transplant recipients was examined in a French study in which 69 of 874 heart transplant patients were infected with HBV, most through nosocomial infection during endomyocardial biopsies. HBV infection had little impact on 5-year survival.¹⁹² In a group of 120 lung transplant recipients in Israel, 11 patients with either chronic hepatitis B or receipt of an organ from an HBeAg-positive donor were given lamivudine prophylaxis. Only one patient developed resistance, which responded to treatment with adefovir. Two patients had reactivation of HBV infection with high aminotransferase levels and high HBV DNA levels.²⁶¹

In a study from Taiwan, overall patient and allograft survival after kidney transplantation were not affected by HBV infection despite increased hepatic morbidity.¹²⁴ Of the 113 patients who received kidney transplants between 1986 and 1998, 20 patients were HBsAg positive and nine were positive for both HBsAg and HCV antibody. Of the 20 who were infected with HBV alone, four developed fulminant hepatic failure and died within 2 years of renal transplantation (RT), two developed cirrhosis, and two others developed HCC.¹²⁴ Overall, however, the 5-year survival was not dissimilar in those infected with HBV and those not infected.

Patients with HBV-compensated cirrhosis are at risk for hepatic decompensation after RT. Patients with HBV-decompensated cirrhosis require combined liver and kidney transplantation.⁶⁴ Antiviral treatment has significantly improved graft survival and mortality.^{69,318} Patients with HBsAg positivity should be started on NAs prior to RT, regardless of the baseline liver histology and serum HBV DNA level.¹⁴⁵ NAs should be continued after RT to retain viral load clearance and prevent liver decompensation and fibrosis.⁸⁸

Immunosuppressive therapy after RT predisposes HBV-infected patients to rapidly progressive fibrosing cholestatic hepatitis, even if the underlying liver disease was mild before RT.²²⁹ Antiviral prophylaxis is recommended for HBV-infected patients who undergo RT.

The child most likely to be treated successfully with today's agents is one who acquired HBV beyond infancy, has evidence of immune responsiveness to HBV, and has mild to moderate inflammatory changes on liver biopsy. The child ideally has no other medical problems, and child and family can comply with the regimen and monitoring. A perinatally infected infant may still respond to therapy as long as there is evidence of immune activation, indicated primarily by ALT values consistently at least 1.5 times the upper limit of normal.¹³¹

Even if the child has some success with treatment but remains HBsAg positive, the child is still at risk for HCC or reactivation to HBeAg and HBV. Yearly follow-up of virologic status, determination of α -fetoprotein level, and ultrasonography are recommended by most experts even though clear evidence to support this practice is lacking.

Immunoprophylaxis

A comprehensive strategy to prevent HBV infection, both acute hepatitis B and the sequelae of chronic HBV infection, can eliminate transmission that occurs during infancy, childhood, and adulthood. It has been clearly demonstrated that HBV transmission cannot be prevented through vaccination strategies targeting only the groups considered at highest risk for developing infection. A comprehensive immunization strategy is currently recommended by the Centers for Disease Control and Prevention (CDC).

Two types of products are available for prophylaxis against HBV infection. HBIG provides antibody to HBsAg, which gives temporary (3–6 months) protection by means of passive immunity; it is indicated only in certain postexposure settings. Hepatitis B vaccine evokes active immunity and is recommended for both preexposure and postexposure prophylaxis.

Hepatitis B Immunoglobulin

HBIG is prepared from plasma known to contain a high titer of anti-HBs. The human plasma from which HBIG is prepared is screened for antibodies to HIV and HCV; the process used to prepare HBIG inactivates and eliminates live viruses from the final product. HBIG is used in the postexposure prophylaxis of neonates of HBV-infected women and for susceptible individuals with sexual, needle-stick, or mucosal exposures. It is administered intramuscularly. The dose for infants with perinatal HBV exposure is 0.5 mL/kg. The dose for adults is 0.06 mL/kg. Efficacy ranges from 70% to 95%.¹⁴ HBIG in large doses is used after LT in HBV-infected patients to prevent infection of the allograft. HBIG is typically administered together with the HBV vaccine; however, nucleos(t)ide therapy is the mainstay of treatment even after LT.

Hepatitis B Vaccine

Hepatitis B vaccines are available as single-antigen formulations or are combined with other vaccines. The two licensed single recombinant vaccines are produced by using *Saccharomyces cerevisiae* (common baker's yeast), into which a plasmid containing the gene for HBsAg has been inserted. Purified HBsAg is obtained by lysis of the yeast cells and separation of HBsAg by biochemical and biophysical techniques. Hepatitis B vaccines are packaged to contain 10 to 40 µg of HBsAg protein/mL

after adsorption to aluminum hydroxide (0.5 mg/mL). See Table 157.1 for recommended dosages. Vaccines available in the United States are Recombivax HB and Engerix-B. Recombinant HBsAg is also used in the three combination vaccines available in the United States: Comvax, Pediarix, and Twinrix. The immunogenicity is similar for all preparations. Oral route of vaccination administration is being studied in mice models by a group of researchers in India using hepatitis B surface antigen (HBsAg)-entrapped polycaprolactone nanoparticles in 60- to 90-nm size range coated with Pluronic F127, showing superior antibody response with a higher titer of anti-HBsAg antibody at 2 months following single oral administration compared to other routes of immunization and conventional alum-based HBsAg vaccine.⁸² A recent multicenter, double-blind, comparator-controlled, phase III study (NCT01480258) conducted in Sweden, Italy, and Finland has demonstrated safety and immunogenicity of a hexavalent DTap5-HB-IPV-Hib vaccine (Infanrix hexa) to be given at 2, 4, and 11 to 12 months of age to be comparable with the analogous component vaccines,^{196,262} which may improve hepatitis B vaccination coverage rates.

The recommended series of three intramuscular doses of hepatitis B vaccine induces a protective antibody response (anti-HBs) in more than 90% of healthy adults and in more than 95% of infants, children, and adolescents. Hepatitis B vaccine should be administered into the deltoid muscles of adults and children or the anterolateral thigh muscles of neonates and infants; the immunogenicity is substantially lower when injections are administered into the buttocks. When hepatitis B vaccine is administered to infants at the same time as other vaccines, separate sites in the anterolateral thigh may be used for the multiple injections.

The vaccination schedule used most often for adults and children has been three intramuscular injections, the second and third administered 1 and 6 months after the first. Each of the two available vaccines has been evaluated to determine the age-specific dose at which an optimal antibody response is achieved.

Perinatal transmission of HBV can be prevented effectively if the HBsAg-positive mother is identified and if her infant receives appropriate immunoprophylaxis. Administration of HBIG and the first dose of hepatitis B vaccine within 12 hours of birth prevents 90% of perinatal infections.¹³⁷ Serologic testing of infants who receive immunoprophylaxis to prevent perinatal infection should be performed to identify the 5%

TABLE 157.1 Recommended Dosages for Hepatitis B Vaccines

Age Group	SINGLE-ANTIGEN VACCINE				COMBINATION VACCINE					
	Recombivax HB		Engerix-B		Comvax ^a		Pediarix ^b		Twinrix ^c	
	Dose (µg) ^d	Volume (mL)	Dose (µg) ^d	Volume (mL)	Dose (µg) ^d	Volume (mL)	Dose (µg) ^d	Volume (mL)	Dose (µg) ^d	Volume (mL)
Infants (<1 y)	5	0.5	10	0.5	5	0.5	10	0.5	NA ^e	NA

^aCombined hepatitis B-*Haemophilus influenzae* type b conjugate vaccine. This vaccine cannot be administered at birth, before age 6 weeks, or after age 71 months.

^bCombined hepatitis B-diphtheria, tetanus, and acellular pertussis-inactivated poliovirus vaccine. This vaccine cannot be administered at birth, before age 6 weeks, or at age ≥7 years.

^cCombined hepatitis A and hepatitis B vaccine. This vaccine is recommended for persons aged ≥18 years who are at increased risk for both hepatitis B virus and hepatitis A virus infections.

^dRecombinant hepatitis B surface antigen protein dose.

^eNot applicable.

^fAdult formulation administered on a 2-dose schedule.

^gHigher doses might be more immunogenic, but no specific recommendations have been made.

^hDialysis formulation administered on a 3-dose schedule at ages 0, 1, and 6 months.

ⁱTwo 1.0-mL doses administered at one site, on a 4-dose schedule at ages 0, 1, 2, and 6 months.

From Mast EE, Margolis HS, Fiore AE, et al. A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices (ACIP) part 1: immunization of infants, children, and adolescents. *MMWR Recomm Rep*. 2005;54(RR-16):1–31.

of infants who become HBV carriers despite these measures. Testing for anti-HBs and HBsAg in children 12 to 15 months of age determines the success of vaccination and, in the case of failure, identifies HBV-infected infants or those who may require treatment or revaccination. The following are the current recommendations as to timing of immunizations for infants in the United States.¹⁹⁸

- *Infants born to HBsAg-negative mothers* should receive the first single-antigen vaccine dose at birth or before hospital discharge. The plan thereafter depends on whether a single antigen or combination vaccine is used. For single-antigen vaccine, the second dose should be administered at age 1 to 2 months and the third at age 6 to 18 months. If combination vaccines are used, the first dose should be of a single-antigen vaccine at birth or before hospital discharge. The second dose should be at 2 months, the third at 4 months, and a fourth dose at either 6 months or 12 to 15 months, depending on the combination of vaccines used. Testing for serologic response is not necessary and is not recommended.
- *Infants born to HBsAg-positive mothers* should receive 0.5 mL of HBIG and the first dose of single-antigen hepatitis B vaccine within 12 hours of birth, administered intramuscularly at separate sites. The infant can then complete the immunization series with either single-antigen or combination vaccine. Premature infants of HBV-infected women should receive the vaccine on the same schedule, but those weighing less than 2000 g at birth have a decreased response to hepatitis B vaccination younger than 1 month old. For such infants, the dose given at birth should not be counted as the start of the vaccine series, and three additional doses of vaccine (for a total of four doses) should be administered beginning when the infant reaches 1 month of age.¹⁹⁸
- *Infants born to mothers whose HBsAg status is unknown* should receive the first dose of vaccine within 12 hours of birth. Meanwhile, a maternal blood sample should be sent for HBsAg testing. If positive, HBIG should be given as soon as possible (no later than 1 week of age). The infant then should complete the routine vaccination schedule. If the infant is preterm and weighs less than 2000 g and the mother's HBsAg is not established within 12 hours of birth, the infant should receive HBIG and single-antigen hepatitis B vaccine and then complete four doses of hepatitis B vaccinations.

Despite the use of hepatitis B vaccine and HBIG in infants born to HBsAg-positive mothers, a portion of infants are still non- or low responders or have immunoprophylaxis failure. A large multicenter study in China demonstrated an immunoprophylaxis failure rate of 3.4% (39/1150). HBeAg-positivity and high viral load (HBV DNA $\geq 6 \log_{10}$ copies/mL) were associated with the greatest transmission and highest immunoprophylaxis rate. Antepartum HBIG had no significant effects on HBV mother-to-infant transmission³²⁷ and is currently not recommended for the mother to prevent vertical transmission of HBV. Meta-analysis of 7561 Chinese participants showed estimated rates of immunoprophylaxis failure of infants with HBsAg-positive and HBeAg-positive mothers to be 4.87% and 9.66%, respectively.¹⁷⁸ Zou et al. retrospectively examined 621 infants of HBsAg-positive mothers in Beijing who received three doses of 10 μ g HB vaccine (at 0, 1, and 6 months of age) and two doses of 200 IU HBIG (at birth and 2 weeks of age) and found a comparable immunoprophylaxis failure rate of 2.9% (0% and 5.2% for infants of HBeAg-negative and HBeAg-positive mothers, respectively).³³⁰

Testing for serologic response (HBsAg and anti-HBs) should be done in infants born to HBsAg-positive mothers when the child is 12 to 15 months of age. If anti-HBs response is inadequate (<10 mEq/L) and the child is HBsAg negative, the child should be revaccinated. If the child's anti-HBs titers are greater than 10 mU/L and the child is HBsAg negative, that child is immune and not infected. If the child is HBsAg positive at age 12 to 18 months, the child should be considered as potentially chronically infected and followed appropriately (Box 157.1).

Others who should receive hepatitis B vaccine. All nonimmunized children and young adults younger than 19 years of age should begin HBV vaccination at any health care provider visit. For older children and adolescents aged 11 to 15 years, the routine three-dose schedule may be used, but a two-dose schedule of vaccination also has been

approved, using the Recombivax HB vaccine. The adult dose (1.0 mL/10 μ g) is administered to the adolescent, and the second dose is given 4 to 6 months later. Short-term (2-year) follow-up in groups immunized by either schedule showed similar rates of anti-HBs decline. Of importance is that a lower dose of vaccine is used in the three-dose schedule; if the original dose is not known, the full three-dose schedule should be used.⁴² Immunization also should be offered to high-risk groups, although universal childhood immunization has created an immune adult population for the most part, except immigrants, who comprise the largest reservoir of adult HBV infection in the United States.

In a three-dose schedule, increasing the interval between administrations of the first and second doses of hepatitis B vaccine has little effect on immunogenicity or final antibody titer. The third dose confers optimal protection, acting as a booster dose. Longer intervals between the last two doses (4–12 months) result in higher final titers of anti-HBs antibodies. Larger vaccine doses (40 μ g) or an increased number of doses is required to induce protective antibody in many hemodialysis patients and other immunocompromised persons (e.g., those who take immunosuppressive drugs or who are infected with HIV). Children with end-stage renal disease respond better than do adults to HBV immunization. Ninety percent of pediatric chronic dialysis patients and 100% of children vaccinated before beginning hemodialysis became anti-HBs positive in one study.⁹⁶ An immunocompromised person who has previously shown an adequate anti-HBs antibody titer that then falls to less than 10 mIU/mL should receive a booster dose.

Testing for immunity (anti-HBs titer) is advised only for patients whose subsequent clinical management depends on knowledge of their immune status (e.g., infants born to HBsAg-positive mothers, hemodialysis patients and staff, patients with HIV infection, LT recipients). Patients who are immunocompromised or on immunosuppressants have been shown to have reduced durable protection from hepatitis B virus vaccine. A cross-sectional study looking at 160 pediatric LT recipients found that the majority (67%) were nonimmune at mean time of 5.6 years from liver transplant despite having received the full HBV vaccination series prior to transplant.¹⁷⁷

Postvaccination testing also should be considered for those at occupational risk who may have exposures from injuries with sharp instruments because knowledge of their antibody response helps determine appropriate postexposure prophylaxis.⁹⁹

When revaccinated, 15% to 25% of people who do not respond to the primary vaccine series produce an adequate antibody response after one additional dose, and 30% to 50% do so after three additional doses.¹³⁰ Therefore, revaccination should be considered for people who do not respond to the initial series.

The duration of vaccine-induced immunity has been evaluated in long-term follow-up studies of both adults and children. The duration of response from neonatal or later immunization is still not clear, but studies in both Asian and European children vaccinated in infancy

demonstrate that immune memory persisted at least 10 years in Italy,³²⁵ was 12 years in Hong Kong,³²² but started to wane by 15 years postimmunization in Taiwanese children.¹⁹¹ Booster doses were administered to the children in the latter study with anti-HBs titers less than 100 mIU/mL, and 4 of 128 demonstrated no response.¹⁹¹ A previous study from the same group demonstrated excellent response in all subjects to a booster dose at age 10 years in those who were anti-HBs seronegative despite neonatal vaccination after being born to HBsAg- and HBeAg-positive mothers.¹²² The timing and necessity of a booster dose are still unclear and not recommended on a population basis.¹³⁸

Therapeutic vaccination—that is, immunization of those already infected in an effort to boost their HBV-specific T-cell responses—has shown limited clinical success in adults. However, a trial of combination immunization (pre-S2/S vaccine) with IFN- α 2b compared with IFN- α 2b alone in children with chronic HBV infection did not show any benefit compared with IFN- α 2b alone.¹¹⁷

Vaccine side effects and adverse reactions. Hepatitis B vaccines are safe for both adults and children. Anaphylaxis is the only serious adverse event in children and adolescents, with a reported observed risk in 2003 of 1.1 per million vaccine doses administered.²⁶ Pain at the injection site (3–29%) and a temperature greater than 37.7°C (99.9°F; 1–6%) have been the side effects most frequently reported, but they were reported no more frequently among vaccinees than among subjects receiving a placebo.^{41,280} In the United States, surveillance from the CDC of adverse reactions has shown a possible association between Guillain-Barré syndrome and receipt of the first dose of plasma-derived hepatitis B vaccine in adults; plasma-derived HBV vaccine is no longer in use.⁴¹ Reports of multiple sclerosis developing after vaccination for HBV led to concern that the vaccine might cause multiple sclerosis in previously healthy subjects, a theory later refuted in a study of large cohorts, as no association was found.^{11,68}

Until 1999, hepatitis B vaccines were prepared with thimerosal (sodium ethylmercuric thiosalicylate) to prevent bacterial and fungal contamination, which aroused public concern regarding mercury toxicity. No adverse outcomes were associated clearly with thimerosal use, but HBV vaccination of neonates was temporarily suspended in 1999 until thimerosal-free vaccines became available. Two thimerosal-free hepatitis B vaccines are now available in the United States for use in infants. Thus, parents can be reassured about the lack of exposure to mercury in hepatitis B vaccines.

Contraindications. There are only a few clinical situations in which hepatitis B vaccine is not recommended: those with a history of anaphylaxis to the vaccine and those with history of acute hypersensitivity to yeast. Vaccination should be deferred in those with an intercurrent moderate to severe illness. Pregnancy is not a contraindication to immunization.¹⁹⁸

Recommendations to Prevent Household Transmission

When a person is found to have acute or chronic infection with HBV, immunization of household contacts is recommended. Guidance on universal precautions should be provided. Parents of infected children and siblings should learn to treat bodily fluids, especially blood, as potentially infectious. All bloody emissions and blood-soiled items should be handled with gloves, and any blood-stained items should be either cleaned with bleach or disposed of carefully. Both the infected person and others in the house should cover skin abrasions with waterproof bandages. Razors and toothbrushes never should be shared. If needle sharps are in use, they should be secured and disposed of according to local guidelines. Schools, workplaces, and health care providers should practice universal precautions for all individuals regardless of whether HBV status is known.

Future Strategies/Targets for Treatment

As new technologies and better understanding of the HBV lifecycle are developed, potential treatments for HBV infection continue to emerge. Several new agents that focus on viral and host targets are under development to cure HBV, including new polymerase inhibitors. Agents targeting cccDNA, such as engineered site-specific nucleases and RNA interference therapeutics, could eliminate cccDNA or silence cccDNA transcription. Inhibitors of HBV nucleocapsid assembly suppress capsid

formation and prevent synthesis of HBV DNA. The HBV entry inhibitor, Myrcludex-B, has been shown to effectively inhibit amplification of cccDNA and the spread of intrahepatic infection. Agents targeting host factors that enhance innate and adaptive immune responses, including the lymphotoxin- β receptor agonist, toll-like receptor agonist, immune checkpoint inhibitors, and adenovirus-based therapeutic vaccine, could play a critical role in the elimination of HBV-infected cells.

Despite advances in treatment, prevention of new infections must remain at the forefront of all therapeutic endeavors. Vertical transmission of HBV to children can be prevented by proper antenatal testing, careful follow-up of results, and availability of immunization programs to infants.

HEPATITIS D

Hepatitis D virus (HDV) is a subviral particle that requires a helper virus, HBV, to establish infection. As a subviral particle, HDV, which also is known as the delta agent or virus, does not encode its own envelope protein and requires HBV envelope production to become an infectious virion. HDV first was described in 1977 when a new antigen was described in the hepatocytes of patients infected with HBV. Transmission experiments demonstrated that the antigen was indeed a new virus.²⁴² Infection with HDV and HBV can be contracted at the same time (coinfection), or HDV can be contracted as a new infection in a person previously infected with HBV (superinfection). There are currently eight major genotypes (clades) of HDV.^{237,244} There is geographic variation in both incidence and genotype distribution.²⁶⁰ HDV genotype 1 is the most frequent genotype found worldwide, but HDV genotypes 2 and 4 are found in the Far East and are associated with milder disease.¹⁷⁵ HDV genotype 1 infection appears to be associated with a more fulminant hepatitis in acute infection and increased rates of cirrhosis and HCC compared with genotype 2.³¹³

Virology

HDV is a spherical particle with a diameter of 36 nm.²⁰⁵ When the envelope is degraded, a nucleocapsid containing hepatitis D antigen (HDAg) and the HDV RNA genome is released. The two forms of HDAg are the small s-HDAg, which is 195 amino acids in length and is required for replication, and the larger l-HDAg, which is 214 amino acids long, is required for virion assembly, and inhibits HDV replication.²⁰⁵ s-HDAg is a nuclear protein that undergoes phosphorylation by protein kinase C, and inhibitors of protein kinase C inhibit HDV replication in cell culture systems.⁵⁸ The ratio of the two forms of HDAg found in patients may vary.

The HDV RNA genome is single stranded and circular, with a length of 1679 nucleotides. During viral replication, the genomic RNA serves as a template for complementary RNA, which, in turn, is a template for more genomic RNA. A host-derived RNA polymerase is required.²⁸⁵ Each copy of the genome and antigenome contains ribozyme activity that cleaves RNA and is required for HDV replication.²⁰⁵ Posttranscriptional modification of the RNA leads to the production of the l-HDAg in addition to the s-HDAg already transcribed.^{58,285}

To leave the host cell, HDV RNA and HDAg must be packaged into virions. The l-HDAg undergoes isoprenylation of a cysteine residue near its C terminus to allow virion assembly. Inhibition of this isoprenylation interferes with viral production by preventing interaction with HBsAg.⁵⁸ Once this interaction occurs, HBsAg and host cell membrane lipids enclose HDV RNA, l-HDAg, and s-HDAg to form virions. Noninfectious HDV particles, which contain only l-HDAg and HBsAg, can be found in serum.²⁰⁵

Epidemiology

The epidemiology of HDV infection parallels that of HBV infection, for obvious reasons. Modes of transmission of HDV also are similar to those for HBV and include direct or indirect parenteral exposure to blood or body fluids and sexual and perinatal transmission. Sexual transmission is less efficient than that of HBV, as evidenced by the relatively low frequency of HDV infection in men who have sex with men.²⁵⁵ Perinatal transmission can occur but is rare because HBV carrier mothers also infected with HDV usually are anti-HBe positive and thus

less infectious. Intrafamilial transmission of HDV has been demonstrated in endemic areas, such as southern Italy, by means of a combined epidemiologic and molecular study, which demonstrated that within family units, the HDV strains were nearly identical.²¹³ Transmission of HDV infection has also been documented among residents of institutions for the developmentally disabled.

The geographic differences in HDV endemicity in the world are great, and four levels have been characterized. High endemicity (i.e., HDV is found in more than 20% of asymptomatic HBV carriers and more than 60% of HBV carriers with chronic liver disease) is seen in northern South America and Africa as well as in Romania.⁴⁷ In these populations, HDV superinfection of HBV carriers is a significant cause of chronic liver disease and causes outbreaks of fulminant hepatitis. In these areas, HDV infection is seen commonly in both children and adults, and household transmission has been implicated. Parts of the Middle East, Africa, some Pacific Islands, and parts of Asia report intermediate HDV endemicity (in 10–20% of asymptomatic HBV carriers and 30–60% of HBV carriers with chronic liver disease). Infection in these regions occurs predominantly in adults, and outbreaks are uncommon, but HDV is an important cause of chronic liver disease. Low endemicity (in 3–9% of asymptomatic HBV carriers and 10–25% of HBV carriers with chronic liver disease) is observed in most developed countries, including the United States, but subpopulations in these countries, such as parenteral drug abusers and prostitutes, have a high infection rate. In areas of low HBV endemicity, transmission of HDV appears to be mainly by the percutaneous route, with higher rates of HDV infection found in intravenous drug users and hemophiliacs than in other HBV high-risk groups. HDV is considered only a moderately important cause of chronic liver disease in developed countries.³¹⁰ Finally, for as yet unexplained reasons, certain subpopulations have a high carriage rate of HBV but virtually no HDV infection; they include American Indians, Alaska Natives, and residents of some Asian countries.

Within the U.S. blood donor population, the prevalence of HDV infection is low; only 1.4% to 8% of donors are infected or have evidence of prior infection.⁹ Estimates from the CDC for 1990 indicate that among the approximately 250,000 cases of acute HBV infection each year, 7500 simultaneously acquire HDV infection. There are about 70,000 carriers of HDV in the United States, where about 1000 deaths per year are caused by chronic HDV and 35 by fulminant HDV. In certain regions, the prevalence of HDV infection appears to be decreasing. In Italy, the prevalence of HDV infection in HBsAg carriers decreased from 23% in 1987 to 14% in 1992 and 8.3% in 1997.^{98,252} Corresponding data for the United States are not available.

Immunopathogenesis

Unlike HBV, HDV is found only in the liver or serum.¹⁰¹ The mechanism by which HDV infection leads to hepatic injury has not been elucidated. Despite some evidence that HDV can be directly cytopathic, cytopathic viruses seldom result in chronic infections. In addition, some HDV carriers have no evidence of hepatic cell damage. Both cellular and humoral components of the host immune system are involved in the response to HDV, although the relative contribution of each is controversial. Investigations into the humoral response to HDV demonstrated that HDAg contains epitopes or immunogenic domains to which sera from acutely infected humans and woodchucks react. The predominantly recognized epitopes are not exposed on the virion surface; thus, antibodies that recognize these epitopes cannot neutralize virus particles, which may explain why no association exists between the humoral response and clinical outcome.²⁰⁵ Autoantibodies, especially liver-kidney microsomal type 3 antibodies and anti-basal cell layer antibody, are found occasionally in people with HDV infection. The significance of these antibodies is unclear, but they may play a role in the immunopathogenesis of HDV.

Cellular immune responses to HDV also have been demonstrated. Both CD4⁺ and CD8⁺ lymphocytes have been found in the liver of patients infected with HDV; it is not clear whether these cells contribute to hepatitis or aid in control of HDV infection.²⁰⁵ Patients with HDV superinfection of chronic HBV who had peripheral CD4⁺ cells that reacted to four epitopes on HDAg were seronegative for HDV IgM,

implying inactive disease.²¹³ Such CD4⁺ T-cell clones produce IFN- γ and may be directly cytopathic. Individuals without these specific CD4⁺ cells had active HDV disease.²¹⁶ These epitopes are in highly conserved regions of HDV, which is encouraging for the prospect of vaccine development.

An unusual mechanism of HDAg presentation by hepatocytes has been reported. The processing of HDAg peptide appears to occur outside the cell, where the peptide is cleaved into smaller fragments that bind to class II major histocompatibility complex molecules of all three human leukocyte antigen types found on hepatocytes and mononuclear cells. This form of antigen presentation could have many possible effects on T-cell responses: amplification of T-cell response to HDAg, stimulation of cytotoxic T cells to kill uninfected hepatocytes, or exhaustion of T-cell responses to HDAg, allowing infected cells to escape detection.²⁰⁵

The relationship of HBV infection status to pathogenesis of HDV is also unclear. Patients with active HBV replication (i.e., HBV DNA and HBeAg seropositive) have high levels of HDV viremia.^{242,243} Conversely, in HBV and HDV carriers without liver disease or with minimal inflammatory hepatic lesions, markers of HBV replication are absent and HDV viremia is low.^{27,243} In coinfecting LT recipients, HDV reinfection can occur without evidence of active HBV replication, but necroinflammatory activity does not develop until HBV infection is reactivated.⁷²

Diagnosis

Establishing the diagnosis of either acute or chronic HBV infection is a prerequisite for the diagnosis of HDV infection, which is made by detection of antibody to HDV (anti-HDV). HDV antigen can be measured in serum, but it is usually present only transiently during acute infection and in immunosuppressed individuals.¹⁷⁵ Radioimmunoassay or enzyme immunoassay kits for the detection of both IgM and IgG anti-HDV are available.

HDV infection may occur at the same time as HBV infection, a pattern that is termed *coinfection*. If an individual has acute, resolving hepatitis B, the HDV infection also will resolve.⁷⁶ In this instance, anti-HDV is found in the IgM form during the acute illness and persists for 2 to 6 weeks. Subsequently, IgG anti-HDV is found in serum, but it also diminishes to undetectable levels when the HBV infection resolves (Fig. 157.8). In HDV superinfection, both IgM and IgG anti-HDV are detected. Most often, superinfection with HDV leads to chronic HDV infection, diagnosed by persistence of both IgM and IgG anti-HDV. Anti-HDV becomes predominantly IgG after about 6 weeks and persists if infection does not resolve; titers correlate well with ongoing viral replication.

Real-time PCR assay quantification of HDV RNA is also now commercially available that can detect all eight genotypes.¹⁵³ Owing to the variability of the HDV genome sequence, HDV RNA assays may yield false-negative results if inadequate primers are used. Therefore, HDV IgM should be tested in patients with negative HDV RNA levels if there is a clinical suspicion for HDV infection or high-risk exposures. Furthermore, quantitative assays of HDV in serum do not correlate with disease activity, although serial measurement of HDV may be useful in monitoring response in treatment.³²⁴

Histopathologic features of HDV infection are very similar to those of isolated HBV infection (see earlier discussion). HDAg can be identified in nuclei and, to a lesser extent, in the cytoplasm of infected hepatocytes. Liver biopsies are recommended in adult patients with HDV to grade inflammation and stage liver fibrosis due to the rapid progression to more severe liver disease.²²⁴ There is a lack of substantial pediatric series to make definitive recommendations in children with HDV. In a child with HBV/HDV coinfection with persistently elevated ALT or clinical deterioration out of proportion to known disease, a liver biopsy may guide clinical decision making (more aggressive HBV therapy, primary HDV treatment, or LT consideration).³¹⁷

Clinical Manifestations

In general, coinfection with HDV infection does not have clinical features that distinguish it from HBV infection alone. Symptoms develop 2 months after exposure, are similar to those of acute HBV infection, and usually resolve by 4 months after exposure. However, two peaks in

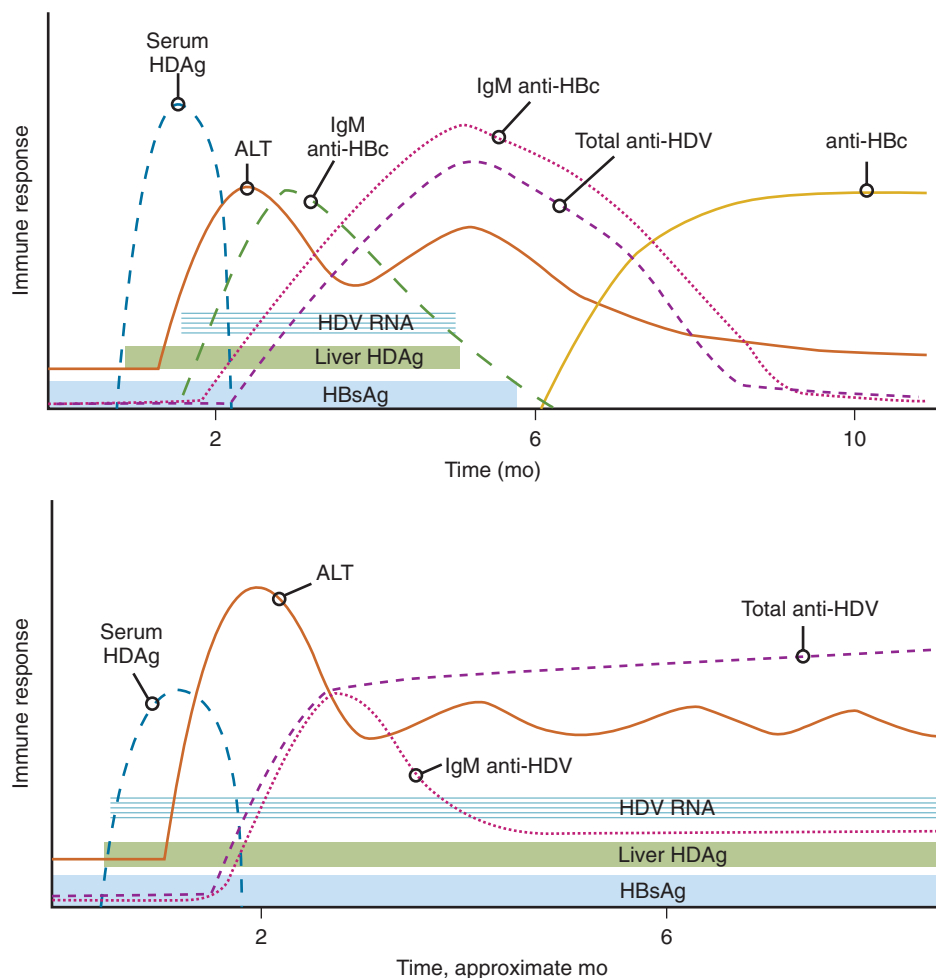

FIG. 157.8 Hepatitis D virus (HDV) serology. Typical serologic course of hepatitis B virus (HBV)-HDV coinfection (*top*) and HBV-HDV superinfection (*bottom*). ALT, Alanine transaminase; anti-HDV, HDV antibody; HBc, hepatitis B core antibody; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HDAG, hepatitis delta antigen; HDV, hepatitis D virus; IgM, immunoglobulin M. (From Xue MM, Glenn JS, Leung DH. Hepatitis D in children. *JPGN* 2015;61:271-281.)

aminotransferase levels often are noted, a pattern that is unusual in HBV infection alone. The infections resolve together.⁷⁷ Coinfection with both viruses does not increase the risk for development of chronic HBV infection.¹⁸⁸

HDV superinfection in individuals with chronic HBV infection has different manifestations. HDV infection becomes persistent in most individuals, and the predominant clinical pattern of chronic HDV infection varies by geographic location. In the United States and Europe, HDV superinfection leads to chronic liver disease in more than 90% of cases, whereas in some Pacific Island and African populations, most individuals with chronic HDV are asymptomatic.²⁴³ When chronic liver disease does occur, the progression to cirrhosis is rapid; in studies in both adults and children, cirrhosis has been noted to occur in as few as 2 to 10 years. The cirrhosis associated with HDV infection has two patterns: in a minority of patients, especially the high-risk drug users, it progresses rapidly to hepatic failure and portal hypertension. In others, more stable cirrhosis occurs, with little inflammatory component, compatible with prolonged survival.³² In a small minority of those who are superinfected, a self-limited hepatitis develops, and subsequently both HBV and HDV infections are cleared. HDV infection has been demonstrated to lead to HCC at a younger age and a higher rate than does HBV infection alone.²⁴³ In a study of 166 patients with HBV and HDV from Romania, the median survival after the diagnosis of HDV-compensated cirrhosis was 58.3 months.¹⁰² A multicenter European study of 200 HBsAg-positive patients with compensated cirrhosis found that 39 (20%) were anti-HDV positive.

Those with HDV, HBV, and cirrhosis were younger than those with only HBV and cirrhosis; indeed, HDV infection may lead to the development of cirrhosis 15 years earlier.⁹¹ In this study, HDV infection increased the risk for HCC three times and risk for mortality twofold compared with those with HBV and cirrhosis.⁹¹ The natural history in those without cirrhosis is difficult to establish. In a study of 13 institutions for those with development disabilities in Illinois, 67 of 238 (28%) of HBsAg carriers also had anti-HDV antibodies.¹¹⁸ Long-term (20 years) follow-up information was available on 65 of 66 anti-HDV- and HBsAg-positive individuals and 166 persons who were HBsAg positive. Liver-related deaths occurred in 7 of 65 (11%) anti-HDV-positive persons but only 1 in 166 anti-HDV-negative persons.² Hepatitis D was associated with both a higher rate of chronic liver disease and a higher liver-related mortality rate.²

A retrospective study of 188 chronically HDV-infected individuals in Italy was performed over an 8-year period. At presentation, 44% of patients had chronic hepatitis, and 56% had cirrhosis. A fourth of the patients with chronic hepatitis progressed to cirrhosis during the study period. In 40 patients, the viremia resolved either while on therapy or spontaneously. Nine percent of patients were diagnosed with HCC during the 8-year follow-up period.²¹⁵

Children with HDV infection follow a course similar to that of adults. In one European series, the subset of children chronically infected with HBV who also were infected with HDV had more advanced liver disease, and the prevalence of HDV infection increased in parallel with the activity of hepatitis. During the study period, disease progressed

more rapidly in children infected with both viruses.⁹⁰ Testing for HDV infection is recommended in any child with chronic hepatitis B and unusually severe liver disease or an acute exacerbation of stable liver disease.

HDV infection after LT can appear without apparent HBV reinfection of either the graft or serum. However, use of PCR assay has demonstrated that low levels of HBV infection do, in fact, occur in patients with recurrent HDV infection, and this replication of HBV is sufficient to permit replication of HDV. The HDV virion found in such infections shares the characteristics of typical HDV infection.³⁰

Treatment

The goal of treating HDV infection is a sustained HDV virologic response as defined by undetectable HDV RNA 6 months after the end of treatment. This may be achieved via the eradication of HBV infection and clearance of HBsAg.³¹⁷ Currently approved regimens include nucleos(t)ide analogs (NAs) and IFN- α , usually in its pegylated form (PEG-IFN). For hepatitis D, PEG-IFN represents the only available treatment option with limited success.

Trials in adults in both Europe and the United States have shown that treatment with either 9 million units three times weekly or 5 million units daily of IFN- α results in normalization of serum aminotransferase levels, decrease or disappearance of HDV RNA from serum, and improvement in hepatic inflammation in about 50% of cases.⁹⁰ However, most patients experienced a relapse shortly after treatment was discontinued. Response maintained after treatment was noted primarily in individuals who became HBsAg negative.

PEG-IFN has been increasingly favored due to its longer half-life, allowing for once weekly dosing. PEG-IFN- α 2b has shown promise as a treatment for chronic HDV in small trials. Fourteen patients were treated with PEG-IFN- α 2b 1.5 μ g/kg weekly for 12 months, and 6 (43%) had a sustained virologic response.³⁹ A recent randomized trial compared a 48-week treatment regimen of PEG-IFN- α 2a plus adefovir, PEG-IFN- α 2a alone, and adefovir alone in 31 patients with HDV. Twenty-three percent of patients treated with combination therapy and 24% of those treated with PEG-IFN- α 2a monotherapy cleared HDV RNA. No patients treated with adefovir alone cleared HDV RNA at 48 weeks.³⁰⁸ Treatment with NAs—including famciclovir, ribavirin, tenofovir, and entecavir alone or in combination with PEG-IFN—has not been proven to be more effective than PEG-IFN alone due to their inability to efficiently eradicate HBsAg, which is necessary and sufficient for enabling the continuous spread of HDV infection.^{1,214,240}

No factors predictive of response have been identified. Prognosis in nonresponders to IFN- α and in those who relapse has been poor. The author of an editorial in *Hepatology* recommended continuation of IFN- α or pegylated IFN- α 2b in patients with a decline in HDV RNA as long as possible, until HDV RNA and HBsAg disappear.⁸⁹

Currently, no recommendations have been established regarding the use of IFN- α or PEG-IFN- α 2b for the treatment of chronic HDV infection in children. A trial in seven children in Greece treated with IFN- α in a dosage of 3 million units/m² of body surface area three times a week for 1 year yielded disappointing results. All remained anti-HDV IgM positive, and four of the seven had persistent HDV RNA in serum. A significant reduction in serum aminotransferase values was noted after 1 year of treatment, but there was no significant improvement in liver histology.⁷⁰ A study of eight children from Germany also found no effect of IFN- α on replication of HDV. However, serum aminotransferase values improved, and children underwent earlier anti-HBe seroconversion compared with historical controls.²⁵⁶

Some children and adults require LT for management of end-stage HDV-associated liver disease. Patients coinfecting with HDV and HBV have lower rates of HBV infection of the allograft than do those in patients with isolated HBV infection. These data were reported in a series of 58 patients with HBV infection, 25 of whom also had HDV infection and underwent LT between 1984 and 1996 in Belgium. Fifty-two patients survived longer than 3 months, and median follow-up was 74 months. HDV infection improved survival at 5 years: 96% \pm 4% compared with 63% \pm 10% for those infected with HBV alone.¹⁷⁶ As yet, no explanation has been given for the better outcome of transplantation in individuals who have both HBV and HDV infections. Administration

of HBIG is required before and after transplantation, as in those patients with HBV infection alone.

Future Therapies

Alternative antiviral agents are being studied for the treatment of HDV infection.²⁹⁴ Farnesylation inhibitors, which inhibit protein farnesyltransferase, are presently being developed to inhibit viral assembly and secretion.^{28,29,65,105,228} In a phase IIa double-blinded, randomized, placebo-controlled study ([ClinicalTrials.gov](https://clinicaltrials.gov), NCT01495585), the oral farnesyltransferase inhibitor lonafarnib, given as 200 mg or 400 mg daily in two doses for 28 days, showed a dose-dependent anti-HDV activity with a 0.74 log (200 mg arm) to 1.54 log (400 mg arm) decrease in HDV RNA.¹⁵⁴ However, although serum HBsAg levels did not change, HDV RNA returned to baseline in all patients after discontinuing therapy, and the more effective 400-mg bid dose was accompanied by substantial gastrointestinal side effects. Longer treatments with lower doses (200–300 mg twice daily for 12 weeks) and ritonavir boosted regimens (100 mg twice daily + ritonavir for 8 weeks) are currently being investigated.³²³

The discovery of the sodium taurocholate cotransporting polypeptides (NTCPs) as the main receptor for HBV and HDV entry has also opened doors for the development of new drugs and strategies to inhibit viral entry and propagation. High-dose conjugated bile salts inhibit NTCP-mediated HDV entry into hepatocytes in vitro but have no impact on serum HDV RNA in chronically HDV-infected individuals.³⁰⁰ Cyclosporine A, which irreversibly binds NTCP, and the cholesterol absorption inhibitor ezetimibe, which acts as a transport substrate for NTCP, both inhibit HBV/HDV entry in cell culture models.²⁹⁴ Myrcludex B, a myristylated PreS1 peptide that competes with HBV/HDV for binding to NTCP, has been shown to prevent HBV/HDV entry and to impair viral dissemination in mice.^{193,227} A phase IIa trial conducted in 40 HBeAg-negative noncirrhotic CHB patients showed a dose-dependent effect on HBV DNA, with greater than 1 log₁₀ HBV DNA decline in 6 of 8 (75%) patients receiving 10 mg subcutaneously (SC) per day of Myrcludex B for 24 weeks but no change in serum HBsAg levels. Treatment was generally well tolerated.²⁹⁴ In a subsequent phase IIa substudy in HBV/HDV-coinfected patients, Myrcludex B at 2 mg SC daily for 24 weeks was associated with anti-HDV activity (6/7 patients >1 log₁₀ HDV RNA decline, 2 patients HDV RNA negative, 2 patients below the limit of quantification, and 4 patients ALT normalization at week 24).²⁵ Oral administration of a liposomal formulation of Myrcludex B has been recently reported.²⁹³ The future role for Myrcludex B remains unclear due to the limited efficacy as monotherapy for HBV. The impact on bile acid metabolism may limit the long-term treatment with Myrcludex B.^{21,22,316} NTCP co-receptors have been identified, including heparan sulfate proteoglycans and, more recently, Glypican 5,³⁰¹ but their potential value as new targets for HBV entry inhibition strategies remains to be established. Other strategies aim to target HBV cccDNA production and processing; viral replication and viral protein expression are being explored. Pediatric trials studying novel HDV therapies are being considered.

Immunoprophylaxis

Passive or active immunization specifically against HDV infection is not available. HDAg itself is highly immunogenic, but antibodies are not neutralizing. Description of a T-cell response to several HDV epitopes in individuals with less severe disease activity has stimulated speculation about possible vaccine development, but studies are preliminary. A DNA-based HDV vaccine successfully induced cellular responses in an animal model and also was successful when used with an HBV vaccine.¹²³ A trial of vaccine derived from B-cell epitopes of HDAg and HDAG p24 expressed in *Escherichia coli*, yeast, or baculovirus in woodchucks provoked a specific antibody response but did not protect against HDV superinfection.⁹⁵

At the present time, individuals with chronic HBV infection who are at risk for acquiring HDV cannot be protected from HDV infection except by avoidance of high-risk behaviors and exposures. However, prevention of HBV infection in susceptible individuals will prevent HDV coinfection and will be the most important mechanism for decreasing the prevalence of HDV infection in a population. The current strategy aimed at decreasing susceptibility to HBV infection by universal

immunization of neonates and catch-up immunization of older children and adolescents should reduce substantially the risk for subsequent development of HDV infection during young adulthood. In Italy, the decrease in HDV prevalence in those with chronic HBV infection from 23% in 1987 to 8.3% in 1997 has led to speculation that chronic hepatitis D may be a “vanishing disease.”⁹⁸
